EXECUTIVE SUMMARY

Background and Key Findings

Traumatic brain injury (TBI) is one of the highest priorities in public health and medicine because of its magnitude, cost, and consequences (e.g., death and disability), and because it is often preventable. The Centers for Disease Control and Prevention's (CDC) National Center for Injury Prevention and Control (NCIPC) estimates that each year approximately 1.7 million civilians in the United States sustain a TBI. Of these TBI injuries, which can occur alone or in combination with other injuries, about 1.36 million are treated and released from emergency departments (EDs), 275,000 are hospitalized, and 52,000 die. However, not all of these ED visits, hospitalizations and deaths are attributable to TBI, but might be due to other co-occurring injuries. These data suggest that the majority of TBIs (approximately 80%; *Coronado, Thurman, Greenspan, and Weissman, 2009*) are mild. These figures might not reflect the true incidence of TBI because they do not include people who are treated in physicians' offices or outpatient facilities or those seeking medical care in non-civilian facilities (*Faul, Xu, Wald, and Coronado, 2010*).

TBI among U.S. military personnel is a critically important health concern for veterans of the current Operation Iraqi Freedom (OIF) and Operation Enduring Freedom (OEF); these operations comprise several subordinate operations in Afghanistan, Horn of Africa, Trans Sahara, Philippines, Kyrgyzstan, as well as earlier theaters of military operations. According

to a Defense and Veterans Brain Injury Center (DVBIC) analysis of surveillance data released by the Department of Defense (DoD), 33,149 U.S. military personnel were diagnosed with a TBI in 2011 alone. This number includes service members (SMs) from the Army, Navy, Marine Corps, Air Force, and from the active duty and reserve components of the National Guard. (*U.S. Dept. of Defense*: http://www.health.mil/Research/TBI_Numbers.aspx). The U.S. Department of Veterans Affairs (VA) estimates that of the 771,874 veterans who sought care from a VA Medical Center from the start of OEF in October 1, 2001 to December 31, 2011, a total of 59,218 unique OEF and OIF veterans were evaluated or treated for a condition possibly related to a TBI (*U.S. Dept. of Veterans Affairs, 2012*: <http://www.publichealth.va.gov/docs/epidemiology/healthcare-utilization-report-fy2012-qtr1.pdf>).

In response to these public health and medical concerns, Congress reauthorized the Traumatic Brain Injury (TBI) Act of 1996 with the passage of the Traumatic Brain Injury (TBI) Act of 2008 (P.L. 110-206; U.S. GPO 2008), which requires CDC and the National Institutes of Health (NIH), in consultation with the Department of Defense and the Veteran's Administration, to

- Determine how best to improve the collection and dissemination of information on the incidence (rate at which new cases of a condition occur in the population) and the prevalence (proportion of a population at any given time that is experiencing the effects of a condition) of TBI among persons who were formerly in the military; and
- Make recommendations on the manner in which CDC, NIH, DoD, and VA can collaborate further on the development and improvement of TBI diagnostic tools and treatments.

This report responds to these mandates. It was developed through a collaborative effort of a Leadership Panel made up of representatives from the four participating agencies/departments and was reviewed, cleared, and approved by the participating agencies/departments. Members of this Leadership Panel were clinicians, researchers, investigators, and science administrators with extensive experience in epidemiologic and clinical research and in treating and managing persons with TBI.

Advances in TBI research in the past 30 years have created new opportunities for improved surveillance and for effective, acute and long-term medical care and rehabilitation; however, as detailed in this report, many important data and knowledge gaps persist. Several critical concerns and challenges related to the population of U.S. SMs who have sustained a TBI while in military service drive the recommendations included in this report. Although DoD and VA have made substantial progress in helping military personnel who have sustained a TBI, critical gaps remain in surveillance, epidemiology, clinical diagnosis, management, and rehabilitation, including a need to continue developing standard surveillance definitions, clinical definitions, and data collection methods as new knowledge and technology emerge. Some recent and current challenges include the following:

- The annual rate of TBI among active duty personnel increased substantially from 2000 to 2011. A majority of the increases occurred from 2006 through 2008 (*U.S. Department of Defense, unpublished data*).

- As is experienced in the general population, the actual rate of TBI among military personnel is potentially underestimated by existing TBI surveillance efforts. This is especially true for identification of personnel who have sustained a mild TBI.
- The total burden of TBI among current and former military personnel, including medical costs, rehabilitation costs and lost productivity/income, is difficult to determine from existing data sources.
- Evidence on the effectiveness of acute and post-acute treatment is limited. Although some guidelines and recommendations exist for the acute and post-acute treatment and rehabilitation of persons sustaining a TBI, they are generally derived from expert consensus or case series studies, as evidence-based scientific knowledge is sparse or is less than optimal to justify the strongest clinical recommendations.
- The influence of blast exposure on the risk for later developing neurodegenerative disorders is unknown.

Recommendations

The following general recommendations were developed in response to these concerns and to the questions posed in the *TBI Act of 2008*:

- **IMPROVE IDENTIFICATION:** Strengthen the identification of military service-related TBI among current military SMs and veterans, including those who do not seek care from the military or VA health-care systems. Emphasis will be given to improving data-collection initiatives and data sources to obtain a more comprehensive picture of the problem and impacts of TBI in this population. All four participating agencies should continue to foster and strengthen collaboration to this aim.
- **STANDARDIZE DEFINITIONS:** Use standard clinical and surveillance definitions and severity classification of TBI among U.S. military and civilian health-care providers and researchers to improve reporting. Update these definitions periodically as more precise, sensitive, and valid terms and definitions are available.
- **STANDARDIZE CLASSIFICATION:** Improve the coding and classification of TBI by working across agencies. All four participating agencies should continue to meet with professional, academic, health care, and coding organizations to discuss improvements in ICD-10-CM and TBI severity measures that can allow comparison of cases and outcomes.
- **ENHANCE DISSEMINATION:** Promote dissemination of information to non-VA facilities regarding TBI services available through the VA health-care system since 2007 including baseline screening and follow-up assessment and evaluation.
- **STRENGTHEN RESEARCH:** Continue research into the consequences of deployment-related TBI, including prospective investigation of the impact of single or multiple insults to the brain and risk for cognitive decline or other health conditions later in life, which might occur among SMs and veterans. Share findings with civilian health-care providers.

- **FOLLOW EVIDENCE-BASED PREVENTION STRATEGIES:** Continue reducing risk factors, improving quality of protective equipment, and ensuring adherence to evidence-based strategies and guidelines.

Evidence indicates that TBI in the U.S. population, including among those who served in the military, is a public health problem, the magnitude and impact of which are underestimated by current civilian and military surveillance systems. Much research is needed to determine the full magnitude of TBI, identify preventable and modifiable risk factors, develop and test strategies to reduce TBIs in civilian and military life, and improve health and social outcomes and quality of life for those who sustain these injuries. Such research will inform the development of more effective primary prevention strategies and policies, diagnostic tools, and therapeutic interventions and will allow for improved rehabilitation and recovery of TBI survivors.

More details on each of the recommendations, including the rationale and potential benefits, can be found in this document. Imperative in planning for the future is recognizing that the public health and medical communities' understanding of TBI is evolving, with many gaps in knowledge for both military and civilian populations. This report offers recommendations for future TBI-related epidemiologic and clinical research; however, refinement and periodic review of the recommendations and their impact will be necessary.

INTRODUCTION

In response to public health concerns, Congress passed the *TBI Act of 2008 (P.L. 110-206; U.S. Government Printing Office 2008)*, requiring the Secretary of the U.S. Department of Health and Human Services (DHHS), acting through the Directors of CDC and NIH, in consultation with the Secretary of Defense and the Secretary of Veterans Affairs, to submit a report on TBI to the relevant committees of Congress. It will contain the findings derived from an evaluation of activities and procedures that can be implemented by CDC to improve the collection and dissemination of compatible epidemiologic studies on the incidence and prevalence of TBI in persons who were formerly in the military. This report addresses that mandate and, as requested by Congress, also includes recommendations on the manner in which CDC, NIH, DoD, and the VA can collaborate further on the development and improvement of TBI diagnostic tools and treatments.

Definition of TBI

TBI was recently defined by a consensus panel of experts “as an alteration in brain function, or other evidence of brain pathology, caused by an external force” (*Menon, Schwab, Wright, and Maas, 2010*).

TBI results from blunt or penetrating trauma to the head, or indirect acceleration and deceleration forces or blasts. These forces might temporarily or permanently disrupt the functioning of the brain. The extent and severity of a TBI after an initial mechanical event depends on many factors, including 1) the magnitude of direct or indirect forces applied to the

head; 2) the direction of the force; and 3) the subsequent direction, duration and amplitude of angular accelerations to which the brain is subjected (Gaetz M. 2004). Other factors influencing the nature and severity of a TBI might include age, sex, body size and weight, comorbidities, alcohol use, genetics, and previous brain injuries, although the evidence on the specific positive or negative effects of each of these is limited. (Förstl, Haass, Hemmer, Meyer, and Halle., 2010; Coronado et al., 2009; Moppett, 2007; León-Carrión, Dominguez-Morales, Barroso y Martin, and Murillo-Cabezas, 2005; D'Ambrosio and Perucca, 2004; Roof, Duvdevani, and Stein, 1993; Pelligrino, Santizo, Baughman, and Wang, 1998). The use of protective gear can reduce the occurrence and severity of brain injuries.

The functional consequences of TBI range from transient, reversible alterations in brain function to profound disability or death. Recovery of neurologic functioning after TBI might or might not occur and varies in its time course from a few minutes to many years. More severe injuries require longer recovery periods. However, even in the case of mild TBI, a subset of persons develop post-concussion syndrome, a syndrome characterized by headaches, depression, irritability, sleep disorder, poor concentration, and fatigue; various studies indicate that 38-80% of those with mild TBI may develop post-concussion syndrome (Hall, Hall, and Chapman, 2005). The effects of a prior TBI on the aging brain are not clear. Multiple severe concussive and sub-concussive injuries, like those reported in boxers who engaged in the sport for several years, are known to cause a delayed dementia syndrome (*dementia pugilistica* or chronic traumatic encephalopathy) (Zetterberg et al., 2006; Zetterberg et al., 2009; McKee et al., 2009; Gavett et al., 2011) that also might be evidenced by a Parkinson-like movement disorder. As described later in this report, case-controlled and cohort studies provide conflicting reports on whether a prior TBI is a risk factor for Alzheimer's disease (Van Den Heuvel C, Thornton, and Vink, 2007; Fleminger S, Oliver, Lovestone, Rabe-Hesketh, and Giora, 2003). Overall, the scope, complexity, and heterogeneity of TBI present challenges for developing precise, sensitive, and accurate diagnostic and prognostic tools and effective medical and other health-related (e.g., rehabilitation) interventions.

PATHOPHYSIOLOGY AND MECHANISMS

TBIs can be classified in many ways (Saatman et al., 2008). For the purposes of this report, TBI is classified as follows: by physical cause, by functional severity, or by the physical changes associated with TBI. The initial impact to the brain in TBI might result in one or more direct effects. For example, a blow to the head from a fall can cause bleeding and bruising of the brain. The result of the initial impact often gives rise to a number of secondary effects that further worsen the severity of the injury.

Brain injuries also can be characterized as focal (localized) or diffuse (widespread); the localization of injury depends primarily on the initial mechanical trauma. The features of TBI include bleeding around the brain or between the brain and the skull, bruising to the brain that is either localized or diffuse. Other features include decreased blood flow to the brain or swelling of brain tissue, which can contribute to complex secondary outcomes. TBI is sometimes also discussed in the context of primary or immediate injury versus secondary or delayed injury. The physical cause of primary injury can be classified as closed, penetrating,

or blast. Classification based on patterns and types of injury is essential for therapy development but is also challenging (*Marshall et al., 1992*).

Primary Injury

Primary injury occurs immediately and as direct result of mechanical trauma. Depending on the injury mechanism and severity, the initial event might cause direct or primary mechanical alterations of the brain tissue (e.g., widespread damage to the axons that provide support and structure to the brain, laceration of the brain, bleeding around the brain or between the brain and the skull, and bruising to the brain). Autopsy studies following fatal TBI have reported large variability in primary and secondary injuries (*Adams, Mitchell, Graham, and Doyle, 1977; Bigler and Maxwell, 2011*). These types of injuries can occur alone or in combination and are often accompanied by other traumatic injuries to multiple organs or body parts.

Secondary Injury

Secondary brain injuries arise from complications initiated by the primary injury itself and via other mechanisms, including inflammation, cell receptor mediated dysfunction, free radical and oxidative damage, and calcium or other ion-mediated cell damage (*Graham, Gennarelli, and McIntosh, 2002*). Primary mechanical changes are generally followed by several biologic processes that occur in the minutes to days following TBI (*Scalea, 2005; Gennarelli and Graham, 2005; Granacher RP, 2007*), resulting in secondary brain injuries that can include the build-up of excess fluid in the brain that gives rise to elevated intracranial pressure (*Granacher, 2007; Porth, 2007; Sullivan et al, 2000; Sauaia et al., 1995*). In turn, these secondary processes modulate gene expression and/or protein regulation that lead either to cell death or repair (*Graham et al., 2002; Luukinen et al, 2005*). Researchers have pursued many of these processes as potential targets for therapies that might limit the extent and severity of injury after TBI.

As in other tissue injuries, an inflammatory reaction to TBI also can occur. Inflammation is involved in the repair of brain tissue after injury, but it can also contribute to secondary brain damage. Secondary injury also might result from other systemic events related to multiple injuries in other organs or body parts; for example, an overall drop in blood pressure might reduce the blood flow to the brain, which contributes to the severity and extent of the initial injury (*Scalea 2005*). Alterations in the regulation of brain blood flow also occur after TBI. Focal constriction of major brain arteries has recently been described after blast TBI (*Bell et al., 2009*). Such large artery vasospasm confined to a small area is considered unusual after non-blast TBI, although it also might be an underappreciated problem (*Shahlaie, Boggan, Latchaw, Ji, and Muizelaar, 2009*). Because the brain is enclosed in the non-expandable skull, brain swelling and hemorrhage added to the intracranial compartment can lead to distortion and compression of brain structures and to raised intracranial pressure (ICP). Elevated ICP after TBI can impede blood flow and thereby cause widespread lack of oxygen to the brain that can result in brain death (*Wijdicks, 1995*).

Focal and Diffuse Injury

TBI can present as a focal (localized) or diffuse (widespread) injury. Some patients may exhibit both focal and diffuse injuries. A focal injury results when bleeding, bruising or a penetrating injury is isolated to a portion of the brain. Focal injury causes neurologic deficits that are related to the functions that take place in the damaged region of the brain. Diffuse brain injury to the axons that connect brain structures is also common, as these “brain wires” provide the major mechanical support to brain tissue and are subject to damaging strain forces upon impact or rapid acceleration/deceleration. Though the neuropathology of blast injury in service members has not been studied systematically, animal studies demonstrate diffuse brain injury after blast trauma (Cernak, 2005). Diffuse brain injury also might occur from rapid acceleration and deceleration forces to the head, a common factor in motor vehicle crashes. The neurologic deficits caused by diffuse brain injury also can affect overall brain function.

Closed: Impact and Acceleration/Deceleration

Impact of the head against another object (Adams, Victor, and Ropper, 1997) can cause focal brain injury under the skull at the site of impact and sometimes at a site on the opposite side of the head, called contrecoup. These focal impact injuries, termed contusions, are prone to bleeding. Bleeding also can occur into other intracranial spaces, including the space that contains the cerebrospinal fluid that surrounds the brain (known as traumatic subarachnoid hemorrhage) and the space underneath the thick leathery dura that is attached to the undersurface of the skull (known as traumatic subdural hematoma). When a skull fracture disrupts arteries that lie over the dura, bleeding might occur between the dura and the skull (epidural hematomas). Intracranial bleeding can lead to death or permanent disability and might worsen over variable periods (minutes to days) post-TBI. Because the skull is a rigid structure and not expandable, the volume of blood that can be accommodated is limited before pressure inside the skull begins to rise and distortion of brain structures occurs. Evacuation of posttraumatic intracranial blood is one of the most common neurosurgical interventions after TBI (Bullock et al 2006).

The most common form of TBI is caused by a combination of impact and acceleration/deceleration forces, such as what occurs in high-speed motor vehicle crashes (Kotapka et al., 1991; Adams, Graham, Murray, and Scott, 1982). Acceleration/deceleration creates forces that can damage the brain even if no actual impact of the head against another object occurs, (although the latter is unusual and requires much higher forces; (Duhaime, 2006]). Impact combined with acceleration/deceleration injury causes shearing of the connecting fibers in the brain. After death, in brains viewed under a microscope, shearing is visible as disruption and focal swelling of the nerve axons. Visualizing shear injury on standard neuroimaging is difficult (Hammond and Wasserman, 2002; Gold and Lipton, 2008). New advanced magnetic resonance imaging (MRI) techniques, might improve imaging of brain lesions, especially those in the mild spectrum and help in the diagnosis of brain injuries. Because these technologies are continuously evolving, they must be refined and validated. (Kirov et al., 2013)

Penetrating Injury

Penetrating TBI occurs when an object enters the brain, whether a bullet, shrapnel, knife, bone fragment, or other material. Penetrating injury is focal because of the mechanical disruption of specific brain regions along the track of the object. However, injury also can occur further away from the object's track because of the transmission of kinetic energy from a high-speed projectile to the brain. Penetrating head injury causes a greater risk of posttraumatic seizures and epilepsy than closed head injury (*Temkin, 2009*).

Blast Injury

Blast injury is the result of pressure waves interacting with the body following exposure to a high-order explosion, that is, an explosive event where the blast pressure front moves rapidly, shattering objects in its path. Though studied in the past, blast injury is subject to more intensive scrutiny since the onset of Operation Enduring Freedom (OEF) and Operation Iraqi Freedom (OIF). The blast environment presents a high risk for penetrating TBI related to shrapnel and forces that cause rapid head movement or impact against other objects, resulting in shear injury or contusion, respectively. Current evidence from animal studies suggests that brain injury can occur as a result of blast pressure waves—even if the wave is directed at the chest (*Courtney and Courtney, 2009*). Whether lung injury itself contributes to brain injury, or whether the structures of the chest participate in transmitting the blast forces to the brain, is not definitively known. For this reason, body armor might offer some brain protection. Although helmets protect the brain from penetrating injury, skull fracture, and contusion, they might not dampen a blast wave and injury may still occur.

The details of how a blast wave causes brain damage are still poorly defined; standard neuroimaging is generally unrevealing. Major questions remain, including the following: What levels of a single blast intensity or distance from the blast are tolerated without permanent injury? Do repeated prior exposures to blast increase vulnerability? Are any longer term-consequences to blast exposure evident? A major gap in understanding is caused by the lack of information about the pathology of blast injury in humans, which is related to limited research on post-mortem brains. In addition, because of the combination of different mechanisms of TBI in the blast area, differentiating the primary blast pathology from those caused by blunt injury, penetrating objects, or shear injury is difficult. Moreover, biological processes that occur as a result of primary and secondary injuries of any external cause, including blast-related TBIs, are not well understood.

Preliminary data suggest that major differences in symptom etiology and pathophysiology are evident between SMs with blast-related closed TBI and non-blast closed TBI (*Moore et al., 2009; Hoffer, Donaldson, Gottshall, Balaban, and Balough, 2009; Hoffer et al 2010*). Scientists have used a brain- imaging technique called diffuse tensor imaging (DTI) to identify the effects of different injury mechanisms. A DTI study comparing blast and non-blast injury determined that blast injuries resulted in more diffuse damage than non-blast injuries. Blast injuries, but not non-blast injuries, were associated with changes in blood flow or structural brain abnormalities (*Moore, 2009; Huang et al., 2009*). In Landstuhl Regional Medical Center, an MRI study of military personnel with a mild TBI diagnosis after exposure to blast demonstrated subtle abnormalities on diffusion imaging in a subset of patients (18/63) (*MacDonald et al., 2011*). Single photon emission CT (SPECT) and positron emission tomography (PET) both demonstrate hypoperfusion (decreased blood flow through an organ) of the frontal lobes, possibly explaining many of the cognitive and behavioral symptoms

associated with mild TBI (Nakayama, Okumura, Shinoda, Nakashima, and Iwama, 2006; Gowda et al., 2006).

Research Relevant to Active Duty Personnel and Veterans

Research collaborations among the four participating agencies (CDC, NIH, DoD, VA) is a fundamental starting point to solving the various problems associated with TBI. Current research is the foundation on which further endeavors can build consensus and effort.

Several clinical trials have attempted to slow secondary processes that contribute to additional damage following TBI. Despite potent neuroprotection of certain chemical compounds in rodent models of head injury, no strategy has so far succeeded in humans. Scientists continue to attempt developing an effective neuroprotective treatment to be administered within hours of the initial trauma to improve patient outcome, including a recently launched multi-center study of progesterone, a treatment modality that demonstrated promise in animal models (*U.S. National Institutes of Health, 2012*). NIH also funds research examining brain recovery after injury. In a collaborative effort, NIH and DoD have established the Federal Interagency TBI Research (FITBIR) Informatics database to facilitate comparison among studies and enhance comparative effectiveness research in TBI.

Studies have found that approximately one-third of SMs with mild TBI also have PTSD (Hoge et al, 2008; Brenner et al, 2009). Because of the overlap in symptoms and this common co-occurrence of PTSD and TBI in SMs, studies related to hormonal differences and imaging findings between PTSD and TBI are ongoing. In the interim, several programs, including those at Fort Campbell, Landstuhl Regional Medical Center, Waco Veterans Affairs Medical Center (VAMC), National Intrepid Center of Excellence in Bethesda, and Cincinnati VAMC have developed programs to treat both mild TBI and PTSD simultaneously.

Without published reports of blast neuropathology in soldiers, scientists are unable to compare what they find in animal models to what is actually happening in persons who have suffered from TBI. To help build pathology data, DoD and others have begun postmortem tissue banks. DoD has developed the TBI Brain Bank through the Armed Forces Institute of Pathology (AFIP), with support from DVBIC, where appropriate patient data and brain specimens of deceased SMs can be archived for further clinical and pathological studies. Officially begun in 2009, this DoD program has the potential to be used for the congressionally mandated 15-year longitudinal study of returnees and veterans of OIF and OEF. Study participants will be invited to consider post-mortem donation of their brains to the DoD TBI Brain Bank as a secondary study arm. In comparison with severe TBI, much less is known about the pathoanatomical or pathophysiological alterations that are produced by mild or concussive injuries, because only in rare cases are these injuries fatal and standard neuroimaging is unrevealing. There may be other opportunities for sharing brain bank resources across agencies to further advance the state of the science.

Research Programs Related to Active Duty Personnel

In the last decade, much work was done to elucidate problems associated with military service-related TBI. A primary focus has been on understanding blast injury (*Lee et al., 2011; MacDonald et al., 2011*) primarily because of the high rate of TBI and blast-related

concussion events resulting from combat operations and the limited knowledge about the blast effects on the central nervous system. These blast-related injuries directly affect the health and safety of individual SMs and thereby also affect the level of unit readiness and troop retention (*Defense and Veterans Brain Injury Center [DVBIC], 2012: <http://www.dvbic.org/about/tbi-military>*). In response, on July 5, 2006, DoD issued DoD Directive 6025.21E “Medical Research for Prevention, Mitigation, and Treatment of Blast Injuries” in compliance with Section 256 of Public Law 109–163 (*U.S. Dept. of Defense, 2006*).

This DoD Directive formally established the DoD Blast Injury Research Program that coordinates and manages the medical-research activities and programs of DoD relating to the prevention, mitigation, and treatment of blast injuries. Through this program, increased funding has been made available for projects that will help identify effects of blast on the brain, mitigate risks, and develop diagnostics and interventions to mitigate brain damage and promote recovery. Through a series of delegations of authority, the United States Army Medical Research and Materiel Command (USAMRMC), a subordinate command of the U.S. Army Medical Command (USAMEDCOM), was selected to carry out the Program's day-to-day coordination and management activities because of its unique position and expertise as the Army's total life cycle medical research, development, acquisition, procurement, and logistical support command (*U.S. Dept. of Defense, 2011: <https://blastinjuryresearch.amedd.army.mil/index.cfm?f=application.introduction>*). Under this research program, studies using advanced imaging techniques have demonstrated that structural pathology associated with persistent symptoms in those with blast-related TBI might be evident (*Peskind et al., 2011; Matthews et al., 2011*). The Blast Injury Research Program is focused on filling gaps in the blast-injury knowledge base. Key research topics by program area, for example, include the following:

- **Acute Treatment:** In this area, DoD is working to
 - Develop diagnostics and neuroprotective drugs for TBI.
 - Develop hemorrhage control and blood products.
 - Develop treatments for psychological trauma.
- **Reset** (a term used in the military to describe a concept that extends beyond rehabilitation to include all activities necessary to return injured SMs to duty or to productive civilian life). In this area, DoD is working to
 - Advance tissue engineering and prosthetics.
 - Improve recovery of physical and mental functioning.
 - Develop return-to-duty standards.

Studies examining the effects of blast injuries are ongoing. Preliminary data suggest that major differences exist in pathophysiology between service members with blast-related TBI and blunt TBI (*Moore et al., 2009*). In a DTI study comparing blast and blunt injury, blast injuries revealed a more diffuse pattern than blunt injuries (*Moore, 2009; Huang et al., 2009*). Blast injuries were associated with abnormalities in the apparent diffusion coefficient, a measure of the movement of water through cell membranes and other parts of the brain, not seen in blunt injuries.

The Breacher Injury Study, conducted by the Defense Advanced Research Projects Agency and the Office of Naval Research (*Applied Research Associates, 2009; Combating*

Terrorism Technical Support Office, 2008) examines the physiological effects or the risks of cognitive impairment as a result of repeated, low-level blast exposures. This is the first prospective study with humans to quantify blast-related TBIs. Aspects of this study were conducted in Breacher trainees (personnel trained to use explosives to gain rapid entry into a facility) from the U.S. Marine Corps' Weapons Training Battalion Dynamic Entry School. The study determined that the trainees did not demonstrate any negative effects due to the exposure. However, the trainers who had greater accumulated exposure over time experienced subtle, reversible cognitive changes after training practices. As a result, the Technical Support Working Group (TSWG) recommended various mitigation measures. The personnel-borne data-acquisition systems used in this study were miniaturized, enabling instrumentation of each Breacher during breaching events. Results of this study are being used to direct future research into protective gear for Breachers (*Applied Research Associates, 2009; Combating Terrorism Technical Support Office, 2008*), and findings can be extrapolated to other branches of the U.S. military to prevent injuries. Understanding the effects of the levels of exposure to blasts on the brain might help to improve surveillance by allowing a better diagnosis and case ascertainment, especially in patients with mild TBIs. Findings from efforts like the Breacher Injury Study might result in better follow up, rehabilitation, and provision of services.

Research Programs Related to Veterans

VA has undertaken various activities to understand better the impact of TBI among veterans. Some of the most persistent and disabling consequences include the ability to select and retain goal-relevant information and to use it for decision-making and goal management in daily life (Ry, Cullen, and Bayley, 2010)—skills that persons without TBI take for granted. Common symptoms of these deficits are being easily distracted, and difficulty with concentration, organization, prioritization, and planning. The VA sponsored two special issues of the *Journal of Rehabilitation Research and Development* that focused on TBI and polytrauma in the veteran population (Department of Veterans Affairs [VA], 2007 & 2009). PTSD, auditory, visual, motor impairment, balance, and other clinical concerns were featured, along with polytrauma, rehabilitation, telemedicine for TBI, and research opportunities. More recently, investigators identified a strong relationship between PTSD and post-concussive syndrome (PCS) and determined that evaluation of both factors is important in clinical management (Benge, Pastorek, and Thornton, 2009). VA researchers are focused on a number of veteran-centric TBI research projects that can be searched through the NIH RePORTER system at <http://projectreporter.nih.gov/> (enter "TBI" in the *Text Search* field and select VA in the *Agency/Institute/Center* field and submit query). Selected relevant publications include the following:

- Evaluation of DTI, Magneto Encephalography (MEG), and Computed Tomography (CT) scans to detect mild TBI indicated that MEG might be more sensitive than DTI and CT scans (Huang *et al.*, 2009).
- A study on visual impairment and dysfunction in SM TBI cases suggests that combat troops exposed to a blast with a mild TBI are at increased risk for visual dysfunction such as blurred vision, difficulty reading or squinting (Brahm *et al.*, 2009).

- A randomized trial comparing cognitive and functional rehabilitation approaches documented better short-term cognitive performance among participants receiving cognitive treatment (Vanderploeg et al., 2008).

DIAGNOSIS

Screening for symptoms possibly associated with TBI involves a quick evaluation of possible exposure to an injury event to determine if an alteration of consciousness (AOC) was evident, if it was associated with the event, or if the event resulted in any neurologic changes or symptoms (*Department of Defense, 2007*). The majority of cases of TBI in the U.S. military are mild TBI and although mild TBIs are often difficult to detect, TBI in persons with multiple trauma—major injuries to the chest, abdomen, pelvis, or extremities—also might be overlooked as other more life-threatening injuries are addressed. Positive TBI screening results should be followed up with a comprehensive evaluation from which a diagnosis is made. This comprehensive TBI evaluation should include identifying the external cause of the patient's injury, assessment for neurobehavioral symptoms, a targeted physical examination, and a follow-up treatment plan.

Pre-Deployment Neurocognitive Baseline Testing

On May 28, 2008, the Assistant Secretary of Defense for Health Affairs (ASD/HA) issued an interim policy letter calling for the Services to “begin implementing baseline pre-deployment neurocognitive assessments for deploying SMs.” The DVBIC was designated the Office of Responsibility for this DoD program known as the Neurocognitive Assessment Tool (NCAT) Program. ASD/HA selected the Automated Neuro-psychological Assessment Metric (ANAM) as the neurocognitive assessment tool; this instrument allows acquiring a baseline assessment of cognitive performance areas most likely affected by mild TBI, including attention, judgment, and memory.

Baseline pre-deployment neurocognitive assessments are administered to all SMs 4–6 months before deployment and sequenced with the pre-deployment training plan (PTP). This sequencing allows the respective commander and command surgeon the timely opportunity to evaluate SMs who might screen positive. This window also provides the greatest opportunity for the unit's medical assets to evaluate, re-evaluate, refer, and begin a medical regimen based upon local treatment protocols. This timeliness allows commanders and medical treatment facilities the opportunity to better manage manpower resources to meet mission requirements.

The goal of this pre-deployment testing is to have the capability to compare assessment results before and after an SM is exposed to a blast event, to improve the detection and treatment of mild TBI. This practice will ultimately affect return-to-duty decisions. From June 2007 through March 2012, 743,309 SMs (35.3% of all who deployed during that period) had completed pre-deployment baseline cognitive testing. The NCAT is used in conjunction with clinical practice guidelines for managing concussion in deployed and non-deployed settings.

The pre-deployment testing program also includes a self-report historical questionnaire screen to determine if TBI or concussion occurred in the past. If an affirmative answer is given in the initial question, additional information is sought regarding loss of consciousness or alteration in consciousness and post-concussive symptoms immediately following the injury and experienced in the 2-year period before testing. The presence of this self-report historical screen and modules other than cognitive evaluation on pre-deployment testing are under review by the Defense Health Board.

In-Theater Screening

In-theater screening occurs immediately following an injury event or as soon as operationally feasible, using the Military Acute Concussion Evaluation (MACE) developed by DVBIC in 2006 (*McCrea, Jaffee, Guskiewicz, and Doncevic, 2009*). MACE allows medics, corpsmen and frontline providers to assess quickly the history of what happened during the event, current symptoms that the SM might experience, a focused neurological exam, and measurement of four cognitive domains: orientation, immediate memory, concentration, and memory recall. The cognitive exam is the Standardized Assessment of Concussion (*McCrea, Kelly, and Randolph, 2000*), which is commonly used as a sideline assessment of sports-related TBI. When combined with other clinical information, this tool helps reveal the presence of any red flags that should prompt an immediate referral because of concerns of a more severe brain injury or to further evaluation and treatment. The currently deployed MACE has been revised substantially (May 2012) and has been validated in combat environments.

In terms of clinical care, before 2010, screening was customarily self-initiated by SMs with potential injury. As a result of an evaluation of in-theater TBI care by both medical and line leadership, concerns were addressed regarding whether this process likely under-evaluated many of those at risk. Subsequently, policy changes now require that every deployed SM involved in a traumatic event, such as motor vehicle collision, and/or within 50 meters of a blast, undergo mandatory medical screening and a 24-hour period of rest (*Department of Defense Instruction 6490.11, 2012*). This practice ensures that all SMs who are involved in a potentially concussive event are screened in a timely fashion to promote early detection of concussion, which will lead to prompt treatment.

SMs with injuries or medical conditions that require evacuation from theater to Landstuhl Regional Medical Center (LRMC) in Germany undergo further evaluation, including screening for concussion or mild TBI using MACE. This process also identifies any history of prior combat or non-combat TBI and assesses for the presence of concussion or mild TBI-related signs and symptoms. Patients with ongoing symptoms are triaged to a stateside medical facility for further evaluation and, if necessary, treatment.

Post-Deployment

Because concussion or mild TBI is not always recognized in theater, screening also occurs through post-deployment health assessments (PDHA). Four questions, adapted from

the Brief TBI Survey (BTBIS) (Schwab *et al.*, 2007), currently appear on the PDHA; positive responses to all four questions prompt a clinical interview to evaluate fully for mild TBI. Although this criterion is more specific than the DoD definition (positive response to questions 1 and 2 only), it allows identification of those with ongoing symptoms who are likely in need of medical services. The Institute of Medicine (IOM) recommended continued use of MACE and BTBIS for screening of combat-related TBI (Institute of Medicine, 2008). Some military treatment facilities perform additional screening. For example, Ft. Carson uses the Warrior Administered Retrospective Casualty Assessment Tool (WARCAT) to fully assess possible injuries (Terrio *et al.*, 2009).

VA Clinical Screening and Diagnosis Tools

Since April 14, 2007, all VA health-care facilities screen all veterans from OEF/OIF for possible TBI upon initial contact with the VA health system (England and Mansfield, 2008; U.S. Dept. of Veterans Affairs VHA Directive 2007-013). Those who screen positive are referred for follow-up evaluations that include a history of the veteran's injury, a physical examination targeted to the veteran's symptoms, and administration of the 22-item Neurobehavioral Symptom Inventory, an inventory that has been adapted by the VA for use in their Comprehensive TBI Evaluation. Veterans Health Administration (VHA) staff received training in administering the screening tool and follow-up evaluation, and the computerized medical record system was modified to include a TBI screening clinical reminder that 1) identifies who needs screening, 2) presents the screening tool to the provider, and 3) enters results into progress notes and into the electronic health record. VA policy requires that a veteran who screens positive be offered a follow-up evaluation with a specialty provider who can determine whether the patient has a TBI and then develop a treatment plan. The evaluation process includes a standardized evaluation template of common problems following brain injury, including a complete TBI-specific eye examination (Schwab *et al.*, 2007).

Civilian Clinical Screening and Diagnosis Tools

The clinical diagnosis of acute TBI in the civilian population is usually based on a history of multiple signs and symptoms, including acute alterations in alertness or consciousness or memory problems that occur immediately after the event. If the traumatic event is witnessed, confirmation of a change in consciousness by an observer (in the context of the mechanical injury) makes the diagnosis. Unconsciousness is usually easy to identify, except if brief, whereas alterations in consciousness might require confirmation through an interview conducted by a medical expert. Most often the witnesses note abnormal behavior, such as disorientation for place or time, poor ability to attend or make new memories, or impaired balance and gait. Sports coaches use standardized tests applied shortly after the injury to diagnose less marked alteration in consciousness in athletes (Lovell, 2009).

In moderate and severe TBI, memory impairment during the period of depressed consciousness results in retrograde amnesia, lack of memory extending back in time, and

impaired memory for details of the injury itself and extending for some time after the injury or anterograde amnesia (*Sigurdardottir Sigurdardottir, Andelic, Roe, and Schanke, 2009*). If unwitnessed, the clinical diagnosis of TBI can be made in the context of a mechanical event involving the head (scalp wound, hematoma, skull fracture, blood behind the tympanic membrane of the ear, or other evidence of a head injury) in someone who has amnesia for the time around the event. Persons with isolated head trauma with minimal alteration in consciousness might not seek medical attention, making unbiased ascertainment of these cases of mild TBI challenging.

Diagnosis is further complicated by other conditions that might cause alteration or loss in consciousness. Alcohol or drug intoxication, hypoglycemia, cardiac arrhythmia, stroke, and seizures can cause rapid change in consciousness and might contribute to falls and other mechanisms of injury that can result in TBI. Although alcohol can contribute to these injuries, including TBIs, the effect of its role after a TBI has occurred is unclear. A study of 38,019 patients with moderate to severe head injuries documented that patients who tested positive for alcohol were less likely to die than patients who had no alcohol in their bloodstream. These patients had more medical complications during their hospital stay and were younger and had less severe injuries (*Salim et al., 2009*). Additional research indicated that high admission blood- alcohol level in patients with isolated moderate to severe TBI was independently associated with improved survival (*Berry et al. 2010; Berry et al., 2011*). These findings suggest that additional research is needed to investigate the potential therapeutic use of alcohol in the management of TBI (*Salim et al., 2009; Berry et al. 2010; Berry et al., 2011*).

The diagnosis of TBI is usually made clinically, and no well-accepted diagnostic tests (e.g., biomarkers or imaging) are available for use in standard medical practice to diagnose mild and even some moderate TBI. However, neuroimaging is commonly used to detect bleeding inside the skull in persons with TBI because posttraumatic bleeding is associated with worse prognosis and can be life threatening. On occasion, such evidence of TBI is discovered on neuroimaging in persons in which the clinical suspicion of TBI was low. Although not all neuroimaging modalities are able to identify all TBIs, some techniques, for example MRI, are better able to identify patients with some potentially critical injuries such as diffuse axonal injury (DAI) (*Belanger, Vanderploeg, Curtiss, and Warden, 2007; Levine et al., 2006*).

Clinical Presentation/Symptoms

Diagnosis of acute TBI is based on several criteria, including history of the event, clinical and functional assessment, and CT scanning and other neuroimaging. Some of the pathoanatomical features of TBI can be diagnosed with neuroimaging. However, standard neuroimaging does not enable comprehensive quantitative assessment of the brain injury, so a substantial discrepancy between the degree of clinical impairment and the degree of injury is often seen on neuroimaging. This is a major clinical concern, especially when trying to understand the neurological mechanisms associated with PCS. Major research advances in neurotraumaproteomics (a study of protein complexes that make up the nervous system) have identified several candidate markers that are under evaluation as TBI biomarkers. Early

research has uncovered several candidates that have shown some preclinical potential; these include lactate dehydrogenase (LDH), glial fibrillary acid protein (GFAP), neuron specific enolase (NSE), and S-100 β . Unfortunately these proteins lack either the necessary sensitivity or brain specificity or both to be used effectively alone (Pineda, Wang, and Hayes. 2004; Pelsers, Hermens, and Glatz, 2005; Ingebrigtsen and Romner, 2003; Bandyopadhyay, Hennes, Gorelick, Wells, and Walsh-Kelly, 2005; Siman et al., 2004). More recently, new candidate biomarkers have been discovered; these include: UCH-L1, MAP-2, and TAU proteins (Kobeissy et al., 2006; Zemlan et al., 1999; Folkerts, Berman, Muizelaar, and Rafols, 1998), and the II-spectrin protein breakdown products (SBDPs) (Pike et al., 2004; Pike et al., 2001; Pike et al., 2000; Ringger et al., 2004; Pineda et al., 2007). These findings highlight the need for biomarker development and validation.

Table 1. Glasgow coma scale

Ability	Score
Eye Opening (E)	
Spontaneous	4
To voice	3
To pain	2
None	1
Motor Response (M)	
Normal	6
Localized to pain	5
Withdraws to pain	4
Flexion-abnormal (<i>an abnormal posture that can include rigidity, clenched fists, legs held straight out, and arms bent inward toward the body with the wrists and fingers bent and held on the chest</i>)	3
Extension (<i>an abnormal posture that can include rigidity, arms and legs held straight out, toes pointed downward, head and neck arched backwards</i>)	2
None	1
Verbal Response (V)	
Normal conversation	5
Disoriented conversation	4
Words, but not coherent	3
No words, only sounds	2
None	1
Score: Eye Score (E) + Motor Score (M) + Verbal Score (V) = 3 to 15	
Teasdale & Jennett, 1974	

Clinical signs and symptoms can occur alone or in combinations and might result in functional impairment. These signs and symptoms appear to be independent of pre-existing conditions except in cases of exacerbation of pre-existing conditions. They usually can be defined by one or more of the three following categories:

Physical: headache, nausea, vomiting, dizziness, blurred vision, sleep disturbance, weakness, paralysis, sensory loss, spasticity, disorders of speech or language, swallowing disorders, balance disorders, disorders of coordination, seizure disorder;

Cognitive: attention, concentration, memory, speed of processing, new learning, planning, reasoning, judgment, executive control, self-awareness, language, abstract thinking;

Behavioral/emotional: depression, anxiety, agitation, irritability, impulsivity, aggression and violence, acting out, noncompliance, social inappropriateness, emotional outbursts,

childish behavior, impaired self-control, impaired self-awareness, inability to take responsibility or accept criticism, or alcohol or drug abuse/addiction. Additional neuropsychiatric problems associated with TBI include apathy, paranoia, confusion, frustration, agitation, sleep problems, or mood swings (*American Psychiatric Association 2000*).

The signs and symptoms listed above are typical of each category but are not an exhaustive list of all possible signs and symptoms.

Severity

TBI is often characterized by severity that is usually based on various clinical factors, including duration or length of LOC, coma scaling, or imaging. Clinicians and investigators have classified TBI as mild, moderate, or severe by scores on the Glasgow Coma Scale (GCS), a widely used scoring system to assess coma and impaired consciousness (*Teasdale and Jennett, 1974; Rimel, Giordani, Barth, Boll, and Jane, 1981; Rimel, Giordani, Barth, and Jane, 1982*). The GCS is an algebraic scale consisting of three components: eye opening, verbal response, and motor response (Table 1). Patients with scores of 8 or less are classified as “severe”; scores of 9 to 12 are “moderate”; and scores of 13 to 15 are “mild” (*National Center for Injury Prevention and Control 2003*).

Although not intended or designed as a severity classification, the LOC duration is often used as an approximation of TBI severity by certain users, including CDC. In addition to brief LOC, mild TBI also might be characterized by confusion or disorientation or loss of memory for events immediately before or after the injury. In contrast, more severe TBI is associated with extended periods of unconsciousness of more than 30 minutes, or prolonged post-traumatic amnesia of more than 24 hours. Although the distinction between mild TBI and more severe TBI seems straightforward, establishing definitive, measurable criteria to identify and quantify the occurrence of mild TBI is challenging because clinicians and investigators have been using different diagnostic criteria and methodologies to study this condition (*Ruff and Jurica, 1999; American Congress of Rehabilitation Medicine, 1993; National Center for Injury Prevention and Control, 2003*).

The DoD and VA classify severity for non-penetrating TBI (Table 2) as mild TBI if the length of time of LOC was 0 to 30 minutes, provided that the patient does not have a clinical or imaging diagnosis indicative of more severe TBI (e.g., a patient with an abnormal imaging who had a LOC of 5 seconds). This LOC-related criterion for mild TBI is consistent with the corresponding CDC criterion and ICD-9- CM classification for concussion (850 series) (*National Center for Injury Prevention and Control, 2003*). DoD and VA also classify TBI as a moderate TBI if the patient has a LOC greater than 30 minutes and less than 24 hours; and severe TBI if the patient has a LOC greater than 24 hours. If a patient meets criteria in more than one severity category, the higher severity level of severity is assigned. CDC concurs with DoD and VA criteria.

Current DoD surveillance methods capture penetrating injury as a separate category, regardless of injury severity because this injury pattern might have more substantial long-term consequences than non- penetrating injury. TBI severity for non-penetrating injuries was determined using standard DoD/VA severity algorithms.

Table 2. DoD/VA severity stratification for non-penetrating TBI

	Mild	Moderate	Severe
Structure Imaging	Normal	Normal or abnormal	Normal or abnormal
Length of Time of Loss of Consciousness	0-30 mins	>30 mins and < 24 hours	> 24 hrs
Alternation of Consciousness/Mental State	A moment up to 24 hrs	>24 hrs Severity based on other criteria	
Post-Traumatic Amnesia	0-1 day	>1 and <7 days	> 7 days
Glasgow Coma Scale*	13-15	9-12	3-8

*For purposes of injury stratification, the Glasgow Coma Scale (GCS) is measured at or after 24 hours (*Malec et al. 2007; Esselman and Uomoto 1995; American Congress of Rehabilitation Medicine, 1993; Saatman et al. 2008; Model System*).

Source: Department of Defense and Department of Veterans Affairs.

Note: Although the initial severity level might have some prognostic value, it does not necessarily reflect the patient's ultimate level of functioning. This requires serial assessments of the patient's cognitive, emotional, behavioral, and social functioning.

If not clinically possible to determine the brain injury level of severity because of medical complications (e.g., medically induced coma), other severity markers are required to determine the severity of the brain injury. For example, one or more of the following may be useful: imaging studies; monitoring intracranial pressure; electroencephalography that may demonstrate absence of electrical brain activity; and, transcranial doppler that may detect the absence of blood flow in the brain.

TREATMENT

Various TBI-related activities are being pursued in the areas of medical care, research, and interagency collaboration.

Persons with isolated mild TBI are usually treated and released from emergency departments. These patients might receive guidance upon discharge regarding when to seek medical care if symptoms persist or worsen and when to return to work, school or sports play (*CDC Heads Up to Clinicians* available at <http://www.cdc.gov/concussion/clinician.html>). In contrast, TBI survivors with moderate to severe injuries are likely to receive treatment in intensive care units and neurosurgical units (*U.S. National Institutes of Health, February 2002*). Treatment depends on the recovery stage of the patient and other factors (e.g., concurrent injuries, comorbid conditions). In the acute stage, the primary aim is to stabilize the patient and to prevent secondary injuries (*U.S. National Institutes of Health February, 2002*). Rehabilitation is the primary treatment for the sub-acute and chronic stages of recovery (*U.S. National Institutes of Health, February 2002*).

Acute Care

TBI care in the Military Health Service (MHS) varies by TBI severity, interval from injury to presentation, and physical location where the injury occurs. In 2005, the Brain Trauma Foundation (BTF), in collaboration with DVBIC and the Uniformed Services

University of the Health Sciences (USUHS), published the *Guidelines for the Field Management of Combat-related Head Trauma* (Knuth et al., 2005). These guidelines relied on extrapolated data from civilian trauma settings and recognized that tactical operations might alter the care that is provided in the combat setting. A decision-tree included in the document gives frontline providers triage decision-making assistance.

Severe and penetrating TBIs are recognized and triaged at the time of injury. Acute care for conditions such as intracranial pressure management, nutrition, and general critical care are consistent with civilian best practices (Bullock and Povlishock, 2007). DVBIC, in conjunction with the American Association of Neuroscience Nurses, supported recommendations for the Nursing Care of Patients with Severe TBI (McIlvoy and Meyer 2008). Military data suggest that patients with combat-related severe and penetrating TBI are at higher risk than patients with less severe or non-penetrating injuries for the development of cerebral vasospasm and vascular injury (Armonda et al., 2006).

To assist with management of acute injury in theater, civilian and military experts developed clinical practice guidelines, Evaluation and Management of Mild TBI/Concussion in the Deployed Setting (Defense and Veterans Brain Injury Center, 2008). These guidelines incorporate consideration of the limited resources available in an austere environment, and the co-morbid psychological health (PH) conditions that might be present. The Guidelines provide indications for urgent CT scanning, strategies for symptom management, and instructions for return to duty evaluations. In most cases, patients with mild TBI can be evaluated and treated at the Forward Operating Base for up to 7 days, or up to 30 days at more sophisticated recovery centers.

In late 2009, Concussion Care Centers were established in Afghanistan to provide supervised rest, education, treatment, and recovery for SMs with concussion. Using this model of primary care decreases the stigma of TBI care, any association with PH, and the development of perceptions of chronic illness. For patients not improving in primary care, specialty referrals and management in a dedicated TBI clinic are indicated. Neurocognitive testing done in theater can be compared with the patient's baseline, thereby better informing return to duty decisions. Since 2010, current DoD guidelines have mandated that deployed service members who are in specific, potentially concussive events will undergo standardized evaluation with MACE, which avoids reliance on self-reporting and broadens in-theater screening from symptom-based to incident-based and includes recommendations for a more detailed evaluation of those sustaining recurrent concussions.

To advance care with best practices, a VA/DoD evidence-based workgroup performed a rigorous literature review and developed a Clinical Practice Guideline for the Management of Concussion/Mild TBI (Defense and Veterans Brain Injury Center & Defense Centers of Excellence, 2008). These guidelines focus on the management of those with sub-acute to chronic injury and include an educational component regarding the natural history of concussion and the expectation of recovery.

Clinical and surgical guidelines have been proposed to guide decisions in TBI treatment, as defined by an authoritative examination of current evidence (Maas, Stocchetti, and Bullock, 2008; Brain Trauma Foundation, 2011). Surgical interventions, such as those for subdural and epidural hematomas, are effective (Bullock et al., 2006). Although some consistency is evident in the clinical management of patients with moderate or severe TBI, which is based upon the best available evidence, few of these management guidelines are based on large, well-controlled clinical trials (Maas et al., 2012). Difficulty in conducting

rigorous studies arises because the pathophysiology of TBI is complex and the disruption in brain function rarely occurs in isolation. Additionally, heterogeneity in neuropathology occurs from person to person (*Jennett, Adams, Murray, and Graham, 2001; Adams, Graham, and Jennett, 2001; Maxwell et al., 2004*). For example, despite success in preclinical or smaller clinical studies, more than 20 drugs or other therapies for moderate or severe TBI have not demonstrated a positive effect on outcome in large, multi-center phase III clinical trials. Numerous explanations for explaining this discordance exist, but the heterogeneity of the patient population is one of the most noteworthy contributing factors (*Narayan et al., 2002; Saatman et al., 2008*). Therefore, nearly all of the treatment guidelines are based on smaller studies and case reports, including medical and surgical interventions to attenuate some types of acute neurotraumatic injuries. A neurosurgical intervention to reduce intracranial pressure, decompressive craniectomy, is one example, although this procedure also remains controversial (*Bullock et al., 2006*). The Brain Trauma Foundation (BTF) has developed guidelines for the management of severe TBI based on the best available evidence (Brain Trauma Foundation, 2007); improvements in outcomes have been reported in an international study when these guidelines were followed (*Arabi et al., 2010*). Similarly, definitive studies to demonstrate the effectiveness of cognitive therapy and other types of rehabilitation are lacking, but numerous smaller studies have provided a basis for rehabilitation guidelines for TBI (*Fadyl and McPherson, 2009; Lane-Brown and Tate, 2009; Cicerone et al., 2008; Borg et al., 2004*). Large-scale comparative effectiveness research that leverages the variability in practice patterns also has been proposed as a means of identifying those treatments associated with better outcome (*Maas et al., 2011*). Despite the lack of class I clinical trials, implementation of guidelines (e.g., the BTF's guidelines) has resulted in improved TBI outcomes (*Bulger et al., 2002; Clayton, Nelson, and Manara, 2004; Elf, Nilsson, and Enblad, 2002; Fakhry, Trask, Waller, and Watts, 2004; Patel et al., 2002; Stein Georgoff, Meghan, Mirza, and El Falaky, 2010; Suarez et al., 2004; Varelas et al., 2006*).

Long-Term Care

Improving continuity of quality care and service delivery along with inter-service, interagency, intergovernmental, and public and private collaboration for care are all critical to the success of long-term care. In addition, management, transition, and associated training, tracking, and accountability for this care are essential for administering such programs. Work in this area includes establishing multiple reforms (e.g., implementing uniform training for recovery coordinators and medical and non-medical care/case managers, establishing a single tracking system, and providing a comprehensive recovery plan for the seriously injured).

The joint Federal Recovery Coordination Program (FRCP) trains and deploys Federal Recovery Coordinators (FRCs) to support medical and non-medical care/case managers in the care, management, and transition of seriously wounded and ill SMs, veterans, and their families.

For veterans and active duty personnel with any loss of vision, blurred vision, or difficulty reading or squinting, VA provides comprehensive vision rehabilitation services—often while the injured SM is still a patient at a military treatment facility. One hundred and sixty four Visual Impairment Service Team (VIST) Coordinators provide lifetime case

management for all legally blind veterans and all OEF/OIF patients with visual impairments. Additionally, 75 Blind Rehabilitation Outpatient Specialists (BROS) with the VA provide blind rehabilitation training to patients who are unable to travel to a center for the blind. These BROS are certified in low-vision rehabilitation and orientation and mobility training and work closely with neuro-ophthalmologists and optometrists who specialize in low vision problems.

VA's Vet Centers

VA's Vet Centers, operated by the Readjustment Counseling Service in the VHA, provide community outreach and professional readjustment counseling services for war-related psychological readjustment problems (*England and Mansfield, 2008*). Vet Centers treat and address PTSD, family relationship problems, lack of adequate employment, lack of educational achievement, social alienation and lack of career goals, homelessness and lack of adequate resources, and other psychological problems such as depression or substance use disorder. They are community-based facilities, located outside of the larger VA medical centers in convenient easy-to-access settings; they embrace a mission that goes beyond medical care in providing a holistic mix of services. Vet Centers offer an alternative to traditional mental health care that helps many combat veterans overcome the stigma and fear related to accessing professional assistance for military-related problems. Eligibility for Vet Center services is based on military service in a combat theater and does not require a veteran to complete the enrollment process.

VA expanded the number of its Vet Centers nationally from 209 in 2007 to 300 facilities and 70 mobile units in 2012.

Since the beginning of OEF/OIF, the focus of the Vet Center program has been on outreach at military demobilization, at National Guard and Reserve sites, and at community locations that feature high concentrations of veterans and family members. To promote early intervention, the Vet Center program hired 100 OEF and OIF veteran returnees to provide outreach services to their fellow combatants. These fellow veteran outreach specialists are effective in mitigating veterans' stigma and establishing immediate rapport. For example, from early in FY 2003 through the end of FY 2007, Vet Centers have provided readjustment services to approximately 268,987 veteran returnees from OEF and OIF. Of this total, more than 205,481 veterans were provided outreach services, and 63,506 were provided clinical readjustment services by mental health providers in Vet Centers such as individual and group counseling for veterans and their families, substance abuse assessment and referral, and screening and referral for medical issues.

VA's Polytrauma System of Care

In its polytrauma system of care (that is, treatment for multiple complex injuries from the same event— for example, amputations, burns, hearing loss, and PTSD), the VA offers comprehensive primary and specialty health care to veterans and seriously injured active-duty service members and is an acknowledged national leader in providing specialty care in the

treatment and rehabilitation of TBI and polytrauma (Feeley 2007). Since 1992, the VA has maintained four specialized TBI Centers that have served as the primary VHA receiving facilities for military treatment facilities seeking specialized care for brain injuries and complex polytrauma. In 2005, the VA established its Polytrauma System of Care, leveraging and enhancing the existing expertise at these TBI centers to meet the needs of seriously injured veterans and active duty service members from operations in Iraq, Afghanistan, and elsewhere.

The mission of the Polytrauma System of Care is to provide the highest quality of medical, rehabilitation, and support services for veterans and active duty service members injured in the service. This integrated nationwide system of care has been designed to provide access to life-long rehabilitation care for veterans and active duty service members recovering from polytrauma and TBI. The polytrauma system of care is composed of four component layers as described below and shown on this map.

Component 1: Regional. The five flagship facilities of the Polytrauma System of Care are Polytrauma/ TBI Rehabilitation Centers (PRC) in Minneapolis, MN; Palo Alto, CA; Richmond, VA; Tampa, FL, and San Antonio, TX. These centers serve as hubs for acute medical and rehabilitation care, research, and education related to polytrauma and TBI. The specialized services provided at each PRC include comprehensive acute rehabilitation care for complex and severe polytraumatic injuries, emerging consciousness programs, outpatient programs, and residential transitional rehabilitation programs. Clinical care specific to TBI is

provided by a staff of rehabilitation specialists and medical consultants in such fields as physiatry (doctors who specialize in physical medicine and rehabilitation), rehabilitation nursing, neuropsychology, psychology, speech-language pathology, occupational therapy, physical therapy, social work, therapeutic recreation, prosthetics, and rehabilitation for blind SMs.

One of the newest programs within the PRCs is the treatment program for patients with severe disorders of consciousness. Provision of rehabilitation services for patients who are minimally conscious or minimally responsive is based on expert opinion rather than scientific evidence. Cornerstones of treatment for patients with severe disorders of consciousness include aggressive medical care to treat potential reversible causes of impaired consciousness (infection, sedation, hormone imbalance); prevention of complications (contracture, pressure sores, malnutrition); family support and education. Additional interventions often include structured sensory stimulation and trials with medications to increase responsiveness. The Disorders of Consciousness Scale is used to monitor response to treatment.

In 2007, staffing for the PRC teams was increased at each center in response to increased demands of patient workload, coordination of care, and support for family caregivers. The PRCs have affiliations and collaborative relationships with academic medical centers, enabling a substantial number of PRC's clinical providers to share VA and affiliated positions in training and medical rehabilitation. The inpatient rehabilitation programs at the PRCs maintain accreditation by the Commission on Accreditation of Rehabilitation Facilities (CARF) for both Traumatic Brain Injury and Comprehensive Rehabilitation.

Component 2: Network. The Polytrauma/TBI Network Sites (PNS), designated in December 2005, represent the second echelon within the Polytrauma System of Care, with one PNS located within each of VA's 21 Veterans Integrated Service Networks (VISN). The PNS provides key components of post-acute rehabilitation care for persons with polytrauma/TBI, including, but not limited to inpatient and outpatient rehabilitation and day treatment programs. The PNS is responsible for coordinating access to VA and non-VA services across the VISN to meet the needs of patients recovering from polytrauma and TBI and their families. The PNS consults, whenever necessary, with the PRC.

Components 3 and 4: Facility. In March 2007, the Polytrauma System of Care network was expanded to include two new components of care: Polytrauma Support Clinic Teams (PSCT) and Polytrauma Points of Contact. With their geographical distribution across the VA, 85 PSCTs facilitate access to specialized rehabilitation services for veterans and active duty SMs at locations closer to their home communities. These interdisciplinary teams manage the care of patients with stable treatment plans, provide regular follow-up visits, respond to new medical and psychosocial problems as they emerge, and consult with their affiliated PNS or PRC when more specialized services are required.

The remaining 40 VA medical centers have an identified Polytrauma Point of Contact who manages consultations for patients with polytrauma and TBI and assists with referrals. The Polytrauma Telehealth Network links the PRC and PNS through state-of-the-art multipoint videoconferencing capabilities. This Network also ensures that polytrauma and TBI expertise are available throughout the system, that care is provided at locations and times most accessible to patients, and that clinical activities include remote consultations and evaluations of patients and education for providers and families.

Another model for using telehealth technology and the sharing of electronic health information along the continuum of care is the rural networks of non-VA health facilities

currently funded by the Health Resources and Services Administration's (HRSA's) Rural Veteran's Health Access Program (RVHAP). A key feature of these networks is collaboration between rural healthcare providers and the Department of Veteran's Affairs. These networks are intended to help eligible entities coordinate innovative approaches, collaborative networks, and virtual linkages to increase the delivery of mental health and other healthcare services to meet the needs of veterans of Operation Iraqi Freedom and Operation Enduring Freedom that reside in remote rural areas.

Coordination and Transition of Care. Care management across the entire continuum is a critical function in the Polytrauma System of Care to ensure lifelong coordination of services for patients recovering from polytrauma and TBI. Consistent, comprehensive procedures and processes have been put in place to ensure transition of patients from military treatment facilities to VA care at the appropriate time, under optimal conditions of safety and convenience for patients and their families. At the direction of the VA's Secretary, 100 Transition Patient Advocates have been recruited nationwide. In addition, the VA assigns a care manager to every admitted patient to coordinate services, address emerging medical, psychosocial, or rehabilitation needs, and provide patient and family advocacy.

To facilitate the continuity of medical care, the PRC receives advanced notice of potential admissions, initiates a pre-transfer review, and follows the clinical progress until the patient is ready for transfer. In addition to record review, clinician-to-clinician communication occurs to allow additional transfer of information and resolution of any outstanding questions.

The DoD and VA also have made substantial progress sharing available electronic health information to further coordinate care. DoD is currently transferring DoD medical digital images and electronically scanned inpatient health records to the VA polytrauma centers from Walter Reed National Military Medical Center, and Brooke Army Medical Center. VA hopes to add the capability to provide this data bi-directionally to support any patients returning to DoD for further care. Additionally, VA and DoD are supporting the secure direct connection of authorized providers at VA polytrauma centers into the health-information systems at Walter Reed National Military Medical Center.

In addition, the Department of Health and Human Services Office of the National Coordinator and the Under Secretary for Health of the Veteran's Health Administration (VHA) have established a Memorandum of Understanding to examine ways to leverage existing resources to develop potential pilot sites for Health Information Exchange between rural providers and the VHA. The VHA Office of Rural Health continues to partner with stakeholders to identify and improve technology adoption in order to expand services to the 3.4 million Veterans that live in highly rural areas.

Psychosocial support for families of injured service members is paramount as decisions are made to transition from the acute care setting of a military treatment facility to a rehabilitation setting. This encompasses psychological support, education about rehabilitation, the next setting of care, and information about benefits and military processes and procedures. VA social worker or nurse liaisons are located at 10 military treatment facilities, including Walter Reed National Military Medical Center. In addition, a Certified Rehabilitation Registered Nurse is available to provide education to the family on TBI, the rehabilitation process, and the PRCs. The Admission Case Manager from the PRC maintains personal contact with the family before transfer to provide additional support and further information about the expected care plan. VA also has benefit liaisons located at military

treatment facilities that refer large numbers of patients to the VA to provide an early briefing on the VA services and benefits available to patients and families.

Lastly, the transition from the PRC to the VA Medical Center in or near the home community must ensure that the treatment plan is maintained. Records for VA medical care are readily available through remote access across the VA system. Follow-up appointments are made before discharge, and the transferring practitioners are readily available for personal contact with the receiving provider to ensure full communication. Care managers at the PNS and the home VA medical center provide ongoing support and problem resolution in the home community, while continually assessing for new and emerging concerns. Finally, each PRC team assesses the expected needs at discharge for transportation, equipment, home modifications, other such needs, and makes arrangements for assessed needs.

Recent studies indicate that the number of medical, physical and psychological injuries that are occurring as a result of combat injury are resulting in a greater functional burden on SM's with the need for integrated, interdisciplinary care, longer acute and inpatient rehabilitation stays and greater health care costs (*Sayer et al., 2008; Schneiderman, Braver, and Kang, 2008*). One of these studies examined long-term treatment in four VA acute PRCs for polytrauma and other combat injuries acquired during the first 4 years of the Global War on Terror (i.e., between October 2001 and January 2006) (*Sayer et al., 2008*). In this study of 188 persons, 56% had blast-related combat injuries; 53% had closed head injuries and 44% had penetrating head injuries; and 56% had craniectomy or craniotomy before PRC admission. Additionally, those with TBI-related blast injury had a significantly greater number of multiple injuries. After rehabilitation, 64% were discharged to home or military bases, 27% to other inpatient service or military treatment facilities, 6% to residential day programs, and 3% to nursing homes. The other was a recent cross-sectional study of veterans following deployment to OEF/OIF examined prevalence of mild TBI and PTSD. In the population surveyed, approximately 12% of 2,235 respondents reported history consistent with mild TBI, and 11% for PTSD (*Schneiderman et al., 2008*).

Care in the Civilian Health System

Transporting severely injured patients directly to the highest level of trauma care (Level I or II trauma centers) has been shown to lower mortality (*Sampalis et al, 1997; Nirula, Maier, Moore, Sperry, and Gentilello, 2010*). Trauma centers demonstrate better adherence to the American Association of Neurologic Surgeons Guidelines for the Management of Severe Traumatic Brain Injury, including immediately available CT scanning, prompt neurosurgical care, and the ability to monitor intracranial pressure (ICP), and treatment of intracranial hypertension (*Hesdorffer and Ghajar, 2007; Fakhry et al, 2004*).

CT scanning is used emergently to identify intracranial bleeding, contusion, or consequences of penetrating injury. These patients might be unconscious on arrival and require stabilization, mechanical ventilation, and intensive care services. In addition, management of co-occurring injuries and meticulous medical care is required to prevent deterioration and the many potential complications, such as infections, acute respiratory distress syndrome, disseminated intravascular coagulation, brain swelling, and multi-organ failure. Monitoring of intracranial pressure is common, and algorithms are in use for lowering

raised intracranial pressure to preserve cerebral blood flow and prevent pressure-related distortion of the brain (herniation syndromes). Intracranial bleeding or hematoma might also require neurosurgical intervention.

Guidelines and Best Practices in Civilian Healthcare Systems

Professional medical societies developed detailed best practice guidelines for the management of severe TBI as shown in Table 3.

Table 3. Guidelines for the management of TBI

Guideline	Source
Guidelines for prehospital management of severe TBI second edition	Badjatia et al., 2006
Guidelines for the management of severe TBI third edition	Brain Trauma Foundation., 2007
Guidelines for the surgical management of severe TBI	Bullock et al., 2006
Guidelines for the acute medical management of severe TBI in infants, children and adolescents second edition	Kochanek et al., 2012
Guidelines for field management of combat-related head trauma 2005	Knuth et al., 2005
The Clinical Policy on Neuroimaging and Decision making in Adult Mild Traumatic Brain Injury in the Acute Setting	American College of Emergency Physicians and CDC (Jagoda et al., 2008)

Although guidelines for neuroimaging and decision making in adult mild TBI exist (Jagoda et al., 2008), there is variability in the use of neuroimaging, decision to admit to hospital or discharge to home, and any follow-up planning (*Miele and Bailes, 2009; Timmons and Winestone, 2009; Heller and Mass, 2009*). Focus is usually on identifying those who are at risk for deterioration, usually caused by post-traumatic intracranial hemorrhage. Many patients with mild TBI are discharged from emergency departments to their home with instructions to return should symptoms worsen. If all goes well, follow-up is usually first suggested with the patient's primary physician but often this follow-up does not occur (*Sosin et al., 1996*). U.S federal agencies, international agencies, and professional organizations have developed best practice guidelines for the management of TBI. For example, the VA and DoD have developed joint clinical practice guidelines for the management of concussion/mild TBI (*U.S. Dept. of Veterans Affairs & U.S. Dept. of Defense, 2009*); the American Academy of Neurology has developed guidelines for neurologists regarding the management of concussion in sports (*American Academy of Neurology, 1997*); the CDC, convening an expert panel, developed guidelines for coaches on how reduce the numbers of mild TBI and how to recognize cases of mild TBI (http://www.cdc.gov/concussion/HeadsUp/online_training.htm); and an expert consensus group from Canada has developed clinical guidelines for mild TBI and persistent symptoms (*Marshall, Bayley, McCullagh, Velikonja, and Berrigan, 2012*). Certain states also have enacted legislation requiring student athletes who sustain a concussion to be seen by a medical expert before they can return to play (*National Conference of State Legislatures, 2013*).

Rehabilitation

A 1998 NIH Consensus Conference on TBI concluded that some evidence supported the use of rehabilitation strategies for TBI, but definitive evidence from large well-controlled clinical trials was lacking. Despite more than 10 years of effort, clinical practice for the rehabilitation of patients with TBI has not advanced substantially. Only limited interventions have demonstrated effectiveness in improving outcomes for patients in rigorous controlled studies (*Vanderploeg et al., 2008; Cicerone et al., 2005; Levine et al., 2000*). One study actually reported that the overall benefit of inpatient cognitive rehabilitation for patients with moderate to severe TBI was similar to that of in-home rehabilitation (*Salazar et al., 2000*). Thus, the translation to wide-scale clinical adoption is still premature. In the absence of strong evidence, and faced with pressing clinical needs, providers have adopted practices based upon consensus and clinical experience (*Fadyl and McPherson, 2009; Lane-Brown and Tate, 2009; Cicerone et al., 2008*). The challenge to develop effective rehabilitation strategies for TBI patients overlaps with those described earlier in this report regarding acute treatment. At the same time, the progress in contemporary neuroscience, imaging, and cell biology is noteworthy—it will ultimately provide the foundation for effective remediation of TBI.

PROGNOSIS AND RECOVERY

Proper identification of the long-term and lifelong medical signs and symptoms of TBI are critical to the study of the epidemiology of TBI-related disability, including the identification of cases of TBI; this however, poses some challenges. Recovery after severe TBI can be protracted. Patients might partially or completely improve after spending weeks, months, or years in states devoid of purposeful behavior; patients might recover their ability to speak, walk, and make new memories. The ability to predict which TBI survivors will recover functional independence in society is poor (*Mushkudiani et al., 2007*).

Moreover, what prompts recovery and the speed, duration, and extent of recovery is not well understood. Predicting the future ability of the severe TBI survivor to return to the workforce is even more difficult. Meticulous medical care in the rehabilitation setting enables recovery, but the role of specific rehabilitation strategies in accelerating recovery after the various forms of TBI is unknown. The majority of scientific investigations of recovery after brain injury focus on focal brain injury, especially stroke. Whether or not the lessons learned from these studies can be extrapolated to TBI is not clear. Intense study of the biology that underlies the recovery processes associated with functional recovery after TBI is warranted.

Gaps in knowledge severely complicate surveillance methodologies and processes to define the burden of illness related to previous TBI. Most difficult is identifying those persons who develop a post-concussive syndrome after a mild TBI. This is further complicated in persons with comorbidities, such as depression, personality disorder, or substance abuse, which can cause some of the symptoms seen in post-concussive syndrome. Another challenge for surveillance of TBI is the lack of a working definition of “full recovery” vs. “persistent disability,” which can occur in persons following TBI.

Recovery from TBI

Recovery after TBI is highly variable (Moppett, 2007) and depends on many factors. Outcomes and recovery can be measured in several forms and aspects. The 25 most common measures used in the field of brain-injury rehabilitation and assessment have been compiled by the Center for Outcome Measurement in Brain Injury (COMBI). COMBI is a collaborative project of 16 brain-injury facilities or centers, most of them Traumatic Brain Injury Model Systems (TBIMS) through grants funded by the Department of Education's National Institute on Disability and Rehabilitation Research (U.S. Dept. of Education, 2012). The most important factor appears to be the severity of the injury (Schretlen and Shapiro, 2003). Milder injuries, which are present in 80% – 90% of TBI survivors, are associated with better outcomes than those with more severe injuries. Many people classified as having a mild TBI might experience complete resolution of symptoms and return to work and other pre-injury activities. Return to work is considered an important metric of recovery, although it is inadequate for children and retired adults and it is important to recognize that many adults with disabilities successfully participate in the workplace. Estimates indicate that 10% – 50% of persons with a mild TBI experience long-term health issues such as persistent headache, difficulty with memory or concentration, or mood changes (Moppett, 2007; Thornhill et al., 2000). Persons who sustain more severe injuries have worse outcomes, with only 20% making a good recovery, as assessed by the Glasgow Outcome Scale (Thornhill et al., 2000). The course of recovery is also faster following mild TBI, occurring largely within 1 – 3 months, compared with 2 or more years in more severely injured groups. In rare cases, and for unknown physiological reasons, recovery from a persistent vegetative state or minimally conscious state can occur years after the TBI (Schiff et al., 2007; Berube et al., 2006). The ability to predict which severe TBI survivors will recover functional independence is poor (Mushkudiani et al., 2007).

A retrospective analysis of data from clinical trials that tested treatments in adults with severe TBI revealed that increasing age was strongly predictive of worse outcomes (Mushkudiani et al., 2007). Race and education also might affect outcomes. Studies have determined that African Americans and Asians with a history of TBI have lower odds of being employed up to 5 years post injury compared with whites who have a history of TBI. (Gary et al., 2009; Berry, Ley, Mirocha, and Salim, 2010). In 1998, another report indicated that persons who were employed at the time of injury, had higher educational levels, and less disability from their injuries were most likely to be employed at 1–3 years after their injury (Gollaher 1998). The reasons for these findings need to be explored further. Some studies suggest that women have worse outcomes following TBI (Slewa-Younan van den Berg, Baguley, Nott, and Cameron, 2009), whereas others report no gender difference (Mushkudiani et al., 2007). Further complicating this picture are animal studies that have demonstrated better recovery in females (Stein, 2004).

Research has demonstrated that the type of injury and certain complications might influence the acute and long-term consequences of TBI. Penetrating injuries have worse outcomes than closed injuries (Wertheimer, Hanks, and Hasenau, 2008). Comorbidities and secondary injuries, such as low blood pressure that might result from severe blood and fluid loss from other injuries, negatively affect outcomes after TBI (Butcher et al., 2007). Genetic factors also might play a role. Certain reports indicate that those persons who have a gene

variant associated with Alzheimer's disease, apolipoprotein E4, also are more likely to have poorer outcomes following TBI (*Nathoo Chetty, van Dellen, and Barnett, 2003; Wilson and Montgomery, 2007*). The majority of experimental preclinical investigations of recovery after brain injury use models of focal brain injury. Clarifying whether this information can be extrapolated to diffuse forms of TBI such as diffuse axonal injury and edema is critical. Intense study of the biology that underlies the recovery processes associated with functional recovery after TBI is warranted.

Post-Concussive Syndrome (PCS)

PCS is a term used to describe disabling symptoms following a neurotraumatic event even when no intracranial pathology is detected with imaging (*Bigler, 2008*). At least two major hypotheses exist regarding the neural substrate for PCS. One is that PCS is caused by diffuse axonal injury, which results in a loss of connectivity between regions of the brain and subsequent behavioral alterations (*Smith, Meaney, and Shull, 2003; Bazarian et al., 2007; Gold and Lipton, 2008*). Diffuse axonal injury is not yet reliably detected with CT scans or other neuroimaging tools, but rapid progress is being made in this area. DTI appears to be a promising diagnostic tool for diffuse axonal injury (*Inglese et al., 2005; Sharp and Ham, 2011*).

A second hypothesis is that persistent metabolic alterations in injured, but not lethally injured, brain cells result in neuronal dysfunction and subsequent behavioral impairments (*Marcoux et al., 2008*). Metabolic alterations following TBI have been reported using sophisticated imaging tools, such as SPECT, PET, and functional MRI, but these methods lack accepted validation for routine clinical use. These hypotheses might both be correct, occurring in separate subsets of persons with TBI. These processes also might both be linked to one underlying mechanism of injury. For example, that metabolic alterations in grey matter are caused by reduced neuronal activity secondary to a loss of connectivity from diffuse axonal injury might be possible.

A better understanding of the pathophysiology of PCS and mild TBI and the development and validation of more sensitive imaging tools is a priority for TBI research. Although many persons seek medical attention immediately or shortly after a TBI, diagnosis can occur at later points in time. Other potential (not yet validated) diagnostic tools for TBI include electroencephalography (EEG); near infrared spectroscopy (NIRS); sensory tests for vision, hearing, and balance, and cognitive and motor assessments (*Suchoff et al., 2008; Arenth, Ricker, and Schultheis, 2007; Pickett, Radfar-Baublitz, McDonald, Walker, and Cifu, 2007*).

Posttraumatic Stress Disorder (PTSD)

PTSD is defined by the DSM-IV criteria as a syndrome occurring in response to a stressor that was a serious threat and the person's response to that threat includes intense fear, helplessness, or horror (*American Psychiatric Association, 2000*). Although PTSD symptoms have been reported in patients with moderate and severe TBI, preliminary data from DoD suggests that TBI patients who have lost consciousness tend not to acquire this condition.

Persons with LOC resulting from TBI and no memory for the traumatic event might not experience the PTSD-like response to the trauma. Similarly, persons with PCS infrequently recall the event or have persistent avoidance of stimuli associated with the trauma. The symptoms of PCS and the PTSD symptom cluster, called hyper-arousal symptoms, tend to overlap. Symptoms such as irritability or outbursts of anger, concentration difficulties, and sleep disturbances occur in both PCS and PTSD and are included in the DSM-IV criteria for PTSD (*American Psychiatric Association, 2000*). They also occur in various physical and psychological disorders. Hypervigilance and excessive startle response are included in the hyper-arousal symptom cluster for PTSD but are not common in PCS. Symptoms common to PTSD appear to occur in greater proportions in those with mild TBI compared with other injuries (*Hoge et al., 2008*). In a study of 2,525 soldiers returning from OEF/OIF, headache was found to be the only symptom with strong association to mild TBI alone (*Hoge et al., 2008*). The approximately one-third of SMs with mild TBI who are also diagnosed with PTSD fare worse on neurocognitive tests of executive functioning and processing speeds than those diagnosed only with mild TBI (*Nelson, Yoash-Gantz, Pickett, and Campbell, 2009; Hoge et al., 2008; Brenner et al., 2009*).

Long-Term Health Outcomes or Disability

The list of neurologic and other problems associated with TBI is long. Cognitive deficits, such as memory impairments, are hallmarks of TBI. Tasks involving complex cognition, including executive function requiring attention, judgment and insight, are particularly problematic for people with TBI, whereas simpler cognitive tasks such as keeping track of daily responsibilities or appointments might not reveal deficits (*Silver, McAllister, and Arciniegas, 2009*).

Neuropsychiatric disorders, including depression, anxiety, PTSD, suicidal tendencies, disinhibition, and substance abuse, have been reported following TBI (*Silver et al., 2009; Belanger et al., 2011*). These neuropsychiatric and emotional disorders might create the most serious challenges to returning to work or other pre-injury activities and to community reintegration. Posttraumatic seizures are common after penetrating head injury or traumatic intracranial hemorrhage; TBI is the largest known risk factor for epilepsy (*Temkin, 2009*).

TBI also can produce movement and sensory disorders that disturb balance, vision, perception, and hearing (*Katz, Zasler, and Zafonte, 2007*). Headaches, pain, sleep disturbances, and fatigue are other frequent symptoms following TBI (*Formisano, Bivona, Catani, D'Ippolito, and Buzzi, 2009; Nampiaparampil, 2008; Rao et al., 2008*). The association of TBI with later development of Alzheimer's disease or chronic traumatic encephalopathy is the subject of continued study.

On December 10, 2012, VA published a proposed rule to amend its adjudication regulations concerning service connection for secondary illnesses associated with TBI. The proposed amendment is in response to a report of the National Academy of Sciences, Institute of Medicine (IOM), *Gulf War and Health, Volume 7: Long-Term Consequences of Traumatic Brain Injury*. The effect of this proposal would be to establish that if a veteran who has a service-connected TBI also has one of five diagnosable illnesses, then that illness will be

considered service connected as secondary to the TBI, which may provide additional benefits to the veteran.

Specifically, VA's proposed regulation states:

- (d) Traumatic brain injury. (1) In a veteran who has a service-connected traumatic brain injury, the following shall be held to be the proximate result of the service-connected traumatic brain injury (TBI), in the absence of clear evidence to the contrary:
 - (i) Parkinsonism following moderate or severe TBI;
 - (ii) Unprovoked seizures following moderate or severe TBI;
 - (iii) Dementias (presenile dementia of the Alzheimer type and post-traumatic dementia) if manifest within 15 years following moderate or severe TBI;
 - (iv) Depression, if manifest within 3 years of moderate or severe TBI, or within 12 months of mild TBI; or
 - (v) Diseases of hormone deficiency that result from hypothalamo-pituitary changes if manifest within 12 months of moderate or severe TBI.

VA received over 200 public comments on the proposed rule and is now preparing the final rule for publication.

Risk of Neurodegenerative Disease Following TBI

Epidemiologic evidence indicates that synergy exists between TBI and permanent neurodegeneration. Longitudinal MRI-based studies have demonstrated brain atrophy occurring in the months to years after TBI (*Ross, 2011*). Contradictory findings regarding the relationship between TBI and Alzheimer's disease exist (*Van Den Heuvel et al. 2007*). Evidence suggests that risk for dementia is increased two to four fold after moderate or severe TBI, but risk following mild TBI is unclear (*Shively, Scher, Perl, and Diaz-Arrastia, 2012*).

Additionally, evidence indicates that repetitive TBI can cause a unique neurodegenerative disorder first reported in boxers and called *dementia pugilistica* (*Martland, 1928*). Now termed chronic traumatic encephalopathy (CTE), this disorder is characterized by the aggregation of the microtubule-associated protein called tau in nerve cells. This is the same protein that aggregates inside dying neurons in Alzheimer's disease and in the brains of persons with a tau gene variant that causes fronto-temporal dementia. Some studies demonstrate that tau aggregation, once started, has the ability to spread from one nerve cell to another; this could explain how an initial focal injury could lead to widespread damage over time (*de Calignon et al. 2012*). The genetic variant apolipoprotein E4, a known risk factor for Alzheimer's disease, has been associated with poorer outcomes after head injury (*Nathoo et al., 2003*) and in some studies with increased risk for the later development of Alzheimer's disease (*Graham et al., 2002; Luukinen et al., 2005; Rabadi and Jordan, 2001; Jordan et al., 1997*). However, this association has not been found in all studies (*Jellinger, 2004*). More recently, CTE has been described in athletes who participated in contact sports and in 21 veterans (86% of whom were also athletes) (*Goldstein et al. 2012; McKee et al., 2009*). Sharing symptoms with PTSD, patients who died with CTE have been described to present

with poor concentration and memory, irritability, depression, and suicidality. The extent of the burden of CTE in service members exposed to TBI is unknown.

SURVEILLANCE

Case Definition Background

Public health surveillance is the ongoing, systematic collection, analysis, interpretation, and dissemination of data on a health-related event, such as TBI, for use in reducing morbidity and mortality and to improve health (CDC, 2001). Surveillance is a labor-intensive process and requires adequate funding, manpower, and, very frequently, a solid public health infrastructure to be successful and sustainable (CDC, 2001). For the purposes of this report and based on accepted requirements for identifying cases for surveillance purposes, CDC and NIH, in consultation with the Secretary of Defense and the Secretary of Veterans Affairs, have defined a case of “traumatic brain injury (TBI) in people formerly in the military” as any combat or non-combat TBI that occurred in a person while serving in the U.S. military (from now on termed *military service-related TBI*) since the beginning of military operations in the first Gulf war on January 17, 1990 (Atkinson, 1993). This time-linked case inclusion criterion can be modified if additional resources become available (i.e., supplementing or changing existing systems).

Surveillance data can be used to estimate the magnitude of a public health problem, understand the natural history of a condition, detect epidemics, document the distribution and spread of a health event, test hypotheses about etiologies, evaluate control measures and develop and implement prevention interventions (Teutsch, 2000).

Standard clinical and surveillance case definitions assist in identifying new cases of TBI and cases with persistent symptoms, impairments, functional limitations, or disabilities resulting from this condition. Historically, each of the departments and agencies involved in this report has used agency/department- specific standard TBI definitions to meet their mandates and needs, but for public health surveillance, the definition described above is used. TBI definitions used by clinicians and investigators may vary, especially for cases of mild TBI (National Center for Injury Prevention and Control, 2003; Culotta, Sementilli, Gerold, and Watts, 1996). The WHO Collaborative Center Task Force on mild TBI published a comprehensive review of definitions. They found that 62% of the definitions reviewed incorporated GCS scores, but differing ranges of scores (13–15, 14–15, or only 15) was evident. LOC or amnesia was required in some definitions, but the duration of LOC varied. The WHO task force concluded that surveillance would benefit from a common definition and collaborated with CDC and other agencies and groups to develop one (Carroll, Cassidy, Holm, Kraus, and Coronado, 2004).

In 2009, TBI researchers from CDC/NCIPC, NIH, DoD, VA, and other federal and nonfederal partners recommended standardized clinical and surveillance case definitions and data elements for TBI research (National Institute for Neurological Disorders and Stroke, 2013). Although certain evidence-based definitions are still under revision due to the paucity of research, their use by all federal agencies and partners might allow better TBI-related research and comparability of data collected in the United States.

Although CDC, NIH, DoD, and VA agree on a common clinical definition for TBI, different perspectives are evident among CDC, Centers for Medicare and Medicaid Services (CMS), NIH, VA, and DoD, and other stakeholder groups, on how to code multiple clinical manifestations of this condition with codes of the International Classification of Diseases (ICD). CDC, NIH, DoD, and VA believe that ongoing interaction and discussion is foundational to advancing TBI-related epidemiologic and clinical research. As more is learned about the natural course of TBI, CDC, NIH, DoD, and VA have committed to continue their collaborations and to extend that to other public and private sector stakeholders and partners to improve and standardize TBI-related definitions (for clinical and epidemiologic purposes), which will be used in all federally funded TBI research. As such, codes of the ICD-9-CM (to identify TBI survivors), ICD-10 (to identify TBI deaths) and the future ICD-10-CM (to identify TBI survivors) classifications will be evaluated continuously. This evaluation process will improve identification of cases of TBI when analyzing ICD-coded administrative or vital statistics databases in the United States. The agencies and partners are committed to this collaborative work that will improve TBI coding and classification, while adhering to structure and conventions of the ICD.

Conceptual and Operational Definitions

To properly and accurately identify patients with TBI, clinicians, researchers, and investigators use conceptual and operational definitions.

A **conceptual case definition** provides criteria to identify a case of TBI for surveillance purposes based on selected clinical signs, symptoms, and neuroimaging. This definition is necessary as a reference standard for the evaluation of operational or working definitions of mild TBI used by surveillance systems.

An **operational case definition** provides quantifiable criteria to consistently identify cases of TBI for surveillance purposes when reviewing ICD-coded health-care administrative or vital statistics databases, when abstracting information from medical records, or when analyzing data from surveys and personal interviews. Operational definitions should be designed to approximate the conceptual definition as closely as possible. Operational definitions might be based on clinical symptoms, clinical records (clinical definition) or based on existing diagnostic coding (e.g., those found in death certificates or administrative hospital data bases).

Clinical Case Definition

CDC issued the following clinical case definition for TBI regardless of injury severity in its 1995 publication, *Guidelines for Surveillance of Central Nervous System Injury* (Thurman *et al.*, 1995).

Clinical Case Definition

For surveillance systems using data from clinical records, a case of TBI (craniocerebral trauma) is defined as an occurrence of injury to the head that is documented in a medical record, with one or more of the following conditions attributed to head injury:*

- observed or self-reported decreased level of consciousness,[†]
- amnesia,[‡]

- skull fracture,
- objective neurological or neuropsychological abnormality,§ or
- diagnosed intracranial lesion**

* Injuries to the head might arise from blunt or penetrating trauma or from acceleration-deceleration forces.

† Decreased level of consciousness refers to partial or complete loss of consciousness. This includes states described as less than full mental capacity, stupor, or coma.

‡ Amnesia might include loss of memory for events immediately preceding the injury (retrograde amnesia), for the injury event itself, and for events subsequent to the injury (posttraumatic amnesia).

§ Neurological abnormalities are determined from neurological examination. Examples include abnormalities of motor function, sensory function, or reflexes; abnormalities of speech (aphasia or dysphasia); or seizures acutely following head trauma. Neuropsychological abnormalities are determined from mental status and neuropsychological examinations. Examples include disorders of mental status (such as disorientation, agitation, or confusion) and other changes in cognition, behavior, or personality.

**Examples of diagnosed intracranial lesions include traumatic intracranial hematomas or hemorrhage (epidural, subdural, subarachnoid, or intracerebral), cerebral contusions or lacerations, or penetrating cerebral injuries (e.g., gunshot wounds). The diagnosis of such intracranial lesions is usually confirmed with a CT or MRI brain scan or by other neurodiagnostic procedures.

The clinical definition of TBI excludes the following:

- lacerations or contusions of the face, eye, ear, or scalp, without other criteria listed above
- fractures of facial bones, without other criteria listed above
- birth trauma
- primary anoxic, inflammatory, infectious, toxic, or metabolic encephalopathies that are not complications of head trauma
- neoplasms
- brain infarction (ischemic stroke) and intracranial hemorrhage (hemorrhagic stroke) without associated trauma

Definition of TBI Based on ICD Diagnostic Coding

The ICD has been used worldwide to code and classify morbidity and mortality data enabling health-care providers to code specific diagnoses. In the United States, some versions of the ICD are used to code and classify mortality data only; since 1999, the tenth version of WHO's ICD-10 (*World Health Organization 1992*) is used to code and classify such data from death certificates.

Clinical modifications (CM) of the ICD have been produced with authorization from WHO to classify morbidity (as opposed to classify mortality). A clinical modification of the

WHO ninth revision of ICD (ICD-9-CM; *Centers for Disease Control and Prevention, 2009*) is being used in the United States to code diagnoses, including those of TBI. To replace ICD-9-CM, a clinical modification of the ICD-10, known as ICD-10-CM, has been developed by CDC/National Center for Health Statistics (NCHS) with input from health-care industry stakeholders; this version will be implemented on October 1, 2014.

TBI Morbidity

Morbidity codes currently in use were last updated in 2001. The ICD-9-CM codes recommended for inclusion in the definition of TBI at this time include the following:

800.0 – 801.9	Fracture of the vault or base of the skull
803.0 – 804.9	Other and unqualified and multiple fractures of the skull
850.0 – 854.1	Intracranial injury, including concussion, contusion, laceration, and hemorrhage
950.1 – 950.3	Injury to the optic chiasm, optic pathways; and visual cortex
959.01	Head injury, unspecified (beginning 10/1/97)
995.55	Shaken Infant Syndrome

Since 2001, additions have been made to ICD-9-CM codes to address emotional and behavioral symptoms of TBI. VA and DoD proposed these additions in response to a request from Congress to address concerns by SMs and veterans who are receiving mental health diagnoses for symptoms of TBI. This is particularly important due to the stigma related to mental health issues as compared to physical injuries. Some of these changes were consistent with ICD and accepted by NCHS. These changes resulted in the inclusion of TBI as a clinical term in ICD-9-CM. VA and DoD also proposed a new code for history of traumatic brain injury (V15.52) and a new code section for signs and symptoms involving emotional state. These new codes allow emotional and behavioral symptoms of TBI and other conditions to be coded without assigning a mental health diagnosis. In addition, VA and DoD have proposed including these codes for several TBI-associated cognitive symptoms.

As the United States starts to replace the current ICD-9-CM coding system with ICD-10-CM, an opportunity exists to improve TBI classification. Federal stakeholders have been concerned regarding the need for a better classification for TBI symptoms using ICD codes as acute or persistent (or chronic) for both epidemiologic and clinical uses. CDC, NIH, DoD, VA, and other federal agencies are reviewing proposed codes of ICD-10-CM classification and making suggestions for changes that would improve TBI reporting in the United States.

Although different perspectives exist among CDC, NIH, DoD, VA and other stakeholders, and because knowledge gaps are apparent regarding the natural course of TBI, these agencies support ongoing interaction and discussion, which is foundational to advancing TBI-related epidemiologic and clinical research. For example, little is known about the pathophysiology and the long-term effects of blast-related TBI. CDC, NIH, DoD, and VA will continue to work together and with other public and private sector stakeholders to 1) standardize all TBI-related definitions to be used in all federally funded TBI research in the United States (*Thurmond et al., 2010; National Institute for Neurological Disorders and Stroke, 2013*) and 2) propose modifications to the ICD-CM that are consistent with the structure and conventions of the classification that will improve identification of cases of TBI in the United States.

TBI Mortality

For TBI Mortality (based on ICD-10 codes). The ICD-10 codes recommended for inclusion in the definition of TBI at this time include the following:

S01.0 – S01.9	Open wound of the head
S02.0, S02.1, S02.3, S02.7 – S02.9	Fracture of skull and facial bones
S04.0	Injury to optic nerve and pathways
S06.0 – S06.9	Intracranial injury
S07.0, S07.1, S07.8, S07.9	Crushing injury of head
S09.7 – S09.9	Other and unspecified injuries of head
T01.0	Open wounds involving head with neck
T02.0	Fractures involving head with neck
T04.0	Crushing injuries involving head with neck
T06.0	Injuries of brain and cranial nerve with injuries of nerves and spinal cord at neck level
T90.1, T90.2, T90.4, T90.5, T90.8, T90.9	Sequelae of injuries of head.

Case Ascertainment by Severity

The use of ICD-9-CM to classify TBI severity is problematic since coding is not consistent with conceptual and clinical definitions for mild, moderate, and severe TBI. This is especially problematic for differentiating mild from moderate TBI. As illustrated by Table 4, persons with LOC 30 minutes to 1 hour would be categorized as mild, rather than moderate since ICD 9-CM, does not differentiate persons with LOC of less than 30 minutes from those with LOC of 30 minutes to 1 hour. Injuries that include brain contusion, hemorrhage, or laceration will be categorized as moderate or severe, depending on LOC and the severity of the focal injury. However, it may not always be possible from ICD-9-CM codes to distinguish between moderate and severe TBI, especially if LOC is not stated. For persons with more than one TBI diagnosis, severity should be consistent with the most severe diagnosis.

Table 4. Stratification of severity by length of time of loss of consciousness

Classification	Mild	Moderate	Severe
DoD/VA Common Definition	0-30 mins	>30 mins and < 24 hrs	>24 hrs
Classification	Brief LOC	Moderate LOC	Prolonged LOC
ICD-9-CM	No LOC; brief <1 hr (30 mins or less, 31 mins to 59 mins)	1 to 24 hrs	>24 hrs
V15.5 DoD/VA Extenders	< 1 hr	1 to 24 hrs	>24 hrs

Source: Department of Veterans Affairs (VA) and Department of Defense (DoD).

Because of these inconsistencies, VA and DoD previously proposed adding synonyms in ICD-9-CM as follows: “mild TBI” for LOC <30 minutes, “moderate TBI” for LOC >30 minutes to <24 hours, and “severe TBI” for LOC > 24 hours. This proposal was intended to

aid clinicians and coders in selecting the correct acute injury code. In the ICD-9-CM review process, the proposals, however, were not supported by stakeholders. VA continues to advocate for a simple revision to ICD-10-CM before the activation in 2014. This revision would eliminate possible coding errors with “concussion” by limiting that section to true concussion (mild TBI, LOC < 30 minutes), and move the remainder of codes in that section to “other intracranial injuries” (S06.89).

DoD V15.5 Code-Related Extenders to Stratify TBI Severity

DoD uses an additional set of internal codes to stratify injury. A series of extenders appended to ICD-9-CM code V15.5 (i.e., personal history of injury) indicate severity based on LOC and to indicate SM's deployment. These extenders are not valid ICD-9-CM codes and are not recognized by other users of the ICD-9-CM classification in the United States. Therefore, any data collected using these codes will be applicable to military settings only. In addition, new V15.5 codes were proposed and implemented (e.g., code V15.52 - History of TBI, was implemented on October 1, 2009).

Mild TBI

In 2003, a CDC Definitions Subgroup of the CDC Workgroup on mild TBI produced and recommended a definition for mild TBI (CDC, 2003). This definition for mild TBI, however, does not categorize other levels of TBI severity (i.e., moderate or severe) and might not be well suited for surveillance of mild TBI not treated in hospital or Emergency Department (ED) settings. Based on this definition (CDC, 2003), the CDC mild TBI Working Group recommended the following three operational or working definitions for case ascertainment based on 1) interviews and surveys; 2) health-care administrative data sets; and 3) clinical records.

Interview/Survey

Mild TBI is recognized when a person or proxy surveyed or interviewed affirms the occurrence, in the period under surveillance, of a nonfatal injury to the head that is accompanied by the following conditions:

- Criteria consistent with the recommended conceptual case definition (occurrence of injury to the head resulting from blunt trauma or acceleration or deceleration forces that result in any period of observed or self-reported transient confusion, disorientation, impaired consciousness, and amnesia around time of injury; or observed signs of other neurological or neuropsychological dysfunction, such as seizures, headache, irritability, fatigue and poor concentration);
- Loss of consciousness or altered consciousness;
- Loss of memory for events immediately before, during, or after the injury.

Surveys and interviews should ask whether health-care professionals evaluated such injuries and, if so, what level of care was provided. Where possible, analyses of data should distinguish among persons who received no medical care, non-hospital-based care which includes physician office visits, hospital emergency department care, inpatient hospital care up to 24 hours, and inpatient hospital care of greater than 24 hours. Unfortunately, these data

have not typically specified whether the TBI or some other injury was the reason for the length of stay, but occurrences of brain injury with inpatient hospital care of greater than 24 hours may be classified as more severe because they do not meet the criteria for mild TBI.

ICD-9-CM Based Definition

Mild TBI is recognized among persons treated in health-care facilities and who are assigned the following ICD-9-CM (International Classification of Diseases, Ninth Revision, Clinical Modification) diagnostic codes:

ICD-9-CM First Four Digits = 800.0, 800.5, 801.0, 801.5, 803.0, 803.5, 804.0, 804.5, 850.0, 850.1, 850.5 or 850.9: 800-804- Skull Fracture; 850-854 Intracranial Injury, excluding those with skull fracture

ICD-9-CM Fifth Digit subclassification is required for categories 851 to 854 to identify loss of consciousness, if any, and the length of time as follows:

- 0, unspecified state of consciousness;
- 1, with no loss of consciousness;
- 2, with brief (less than one hour) loss of consciousness;
- 6, with loss of consciousness of unspecified duration; and
- 9, with concussion, unspecified.

ICD-9-CM First Four Digits = 959.0: Injury, Other and Unspecified

ICD-9-CM Fifth Digit = 1, with no loss of consciousness.

These codes indicate either skull fracture or concussion without evidence of underlying brain hemorrhage or contusion, and no more than brief LOC. It is important to note that although the fifth digit 2 is being used to indicate mild TBI, this ICD-9-CM code is problematic for indicating severity. A fifth digit of 2 indicates loss of consciousness less than 1 hour. As mentioned above (Table 4), the clinical definition used by DoD/VA of mild TBI includes only those patients with loss of consciousness of less than 30 minutes. However, the ICD-9-CM does not differentiate between LOC of less than 30 minutes and 30 minutes to 1 hour. The latter would actually indicate moderate TBI. Thus, use of the fifth digit “2” as mild overestimates the number of persons with mild TBI and underestimates the number of persons with moderate TBI.

Clinical Records Definition. Mild TBI is recognized when the medical records document any one of the following conditions:

- Criteria consistent with the recommended conceptual case definition;
- GCS score between 13 and 15 assigned at the time of first medical evaluation at a health-care facility;
- Abbreviated Injury Severity Scale score of 2 for the head region (*Gennarelli and Wodzin, 2008*).

Exclusions: Injuries accompanied by indicators of neurological deterioration during the course of acute care, such as cases in which subsequent GCS scores fall below 13 are excluded (*NCIPC, 2003*).

TBI-Related Disability

Ascertaining the prevalence of disability attributable to severe TBI relies on medical records, access to supportive services, and school or work status. Persons with severe TBI frequently have residual cognitive or other neurological disability (e.g., weakness, stiffness, slurred speech, incoordination, posttraumatic epilepsy) and commonly require long-term assistance. Patients with severe TBI who survive their injuries frequently require extensive rehabilitation, first as an inpatient and later as an outpatient. Neurological recovery might take place over months or even years; however, many do not recover to independent functioning or enter/re-enter the work place, and carry a diagnosis of chronic brain injury caused by trauma (*Riggio, 2011*).

TBI-related disability is identified over time during the continuum of assessment and management of TBI. Ascertaining the prevalence of disability because of TBI is difficult for mild and moderate TBI. Patients with mild TBI can acquire conditions such as disordered sleep, fatigue, headache, dizziness, poor concentration, anxiety disorder, memory, and depressed mood. While recovery usually occurs during the first few months following injury, 10% – 50% might have symptoms that last more than a year (*Riggio, 2011*). In addition, evidence suggests that persons with repeated events of TBI tend to recover more slowly after each ensuing event and in extreme cases might develop chronic neurodegenerative changes—first seen as *dementia pugilistica* in boxers but now termed chronic traumatic encephalopathy (CTE) (*McKee et al., 2010*).

Specialized survey techniques are necessary to quantify the incidence and duration of post-concussive syndrome. Batteries of standardized neuropsychological testing can determine the level of cognitive function in specific domains: attention, memory, executive function, processing speed, verbal ability, spatial ability, depressed mood, and symptom validity. However, pre-testing is not routinely done for most persons, making these comparisons challenging. Determining pre-injury levels of function is more difficult, but can be estimated based upon previous level of achievement in education or employment. Comparison of scores on pre-injury and post-injury tests of cognitive abilities might be the most reliable means to determine if the effects of TBI are persistent.

Data Sources

Civilian

The primary responsibility for public health surveillance in the civilian system resides at the state level (*Jacobson, Hoffman, and Lopez., 2007; Horan and Mallonee, 2003*). Since the mid-1990s, CDC and at least 30 states have developed injury surveillance systems, including TBI (*CDC State Programs, 2009*); the capacity of these state systems is variable (*CDC unpublished data*). States must improve their capacity to identify all injuries and yet have the specificity to identify TBI events and use linkages between data systems or other indicators to identify veterans with military service-related TBI in all 50 states and territories. A number of civilian health and injury surveillance systems already exist and could incorporate additional measures to capture or validate information specific to TBI and/or military service (Table 5).

Department of Defense

Armed Forces Health Surveillance Center (AFHSC)

The Armed Forces Health Surveillance Center (AFHSC) was established in February 2008 by the DoD to be the central epidemiology health resource for the U. S. military. It merges the capabilities and resources of the Army Medical Surveillance Activity (AMSA), the DoD Global Emerging Infections Surveillance and Response System (DoD-GEIS), and the Global Health Surveillance Activity of the Force Health Protection Directorate of the Office of the Assistant Secretary of Defense for Health Affairs. Also, AFHSC assumed responsibility for AMSA's Defense Medical Surveillance System (DMSS) and the DoD Serum Repository (DoDSR). DMSS contains up-to-date and historical data on diseases and medical events (e.g., hospitalizations, laboratory tests, immunizations) affecting SMs throughout their military careers. DMSS contains over two billion records on nine million service members and other beneficiaries of the MHS.

Table 5. Civilian public health surveillance systems

Name of Surveillance System (in alphabetical order)	Agency	Design and Use
Behavioral Risk Factor Surveillance System (BRFSS)	CDC and health departments in 50 states, District of Columbia, Puerto Rico, Guam, and Virgin Islands	Population based, random-digit dialed telephone survey of adults (aged ≥ 18 years) in the United States; three components: core, optional, state-specific. Used to track health conditions, disability, and risk behaviors and to collect state/territory data on preventive health practices linked to chronic diseases, injuries, and preventable infectious diseases.
CDC Traumatic Brain Injury Surveillance System (CDC TBI SS)	CDC/National Center for Injury Prevention and Control: Core Violence and Injury Prevention Program (VIPP)	Statewide representative ongoing population-based surveillance system. Used to identify, track, and analyze statewide trends in TBI. Information used to inform primary and secondary prevention strategies.
National Ambulatory Medical Care Survey (NAMCS)	CDC/National Center for Health Statistics	Nationally representative multistage probability survey based on a sample of visits to non-federal office-based physicians engaged primarily in direct patient care. Excludes those in anesthesiology, radiology, and pathology. Representative sample used to identify and track ED and outpatient department visits.
National Electronic Injury Surveillance System – All Injury Program (NEISS-AIP)	Consumer Product Safety Commission (CPSC) and CDC/National Center for Injury Prevention and Control	Nationally representative, stratified probability sample of all U.S. hospitals that have at least 6 beds and provide 24 hour ED services. Used to identify, track, and analyze national trends in injury-related ED visits.
National Health Interview Survey (NHIS)	CDC/National Center for Health Statistics	Population-based, nationally representative, face-to-face probability sample survey among civilian, non- institutionalized U.S. population. Used to monitor trends in illness and disability, track progress toward achieving national health objectives, characterize various health problems, determine barriers to access and use of health care, and evaluate federal health programs.
National Hospital Ambulatory Medical Care Survey– Emergency Department and Outpatient Department Modules (NHAMCS)	CDC/National Center for Health Statistics	Nationally representative multistage probability sample of visits to emergency and outpatient departments and to ambulatory surgery facilities in noninstitutional general and short-stay hospitals, excluding Federal, military, and Veterans Administration hospitals, located in the 50 States and the District of Columbia. Used to identify and track ED and outpatient department visits.

Table 5. (Continued)

Name of Surveillance System (in alphabetical order)	Agency	Design and Use
National Hospital Discharge Survey (NHDS)	CDC/National Center for Health Statistics	Nationally representative three-stage stratified sample survey of inpatient hospital records acquired from probability sample of ~500 non-federal short-stay hospitals. Provides information on characteristics of patients of all ages that were hospitalized and discharged from hospitals in sample.
Nationwide Inpatient Sample (NIS)	Agency for Healthcare Research and Quality (AHRQ)	Nationally representative multi-state health data system of all hospital discharges from a stratified probability sample of non-federal short-stay hospitals (40 states; 1,044 hospitals in 2007). Used to identify, track, and analyze national trends in health-care utilization access, charges, quality, and outcomes by diagnoses.
State and Local Area Integrated Telephone Survey (SLAITS)	CDC/National Center for Health Statistics	Collection of broad-based ongoing surveillance systems; uses sampling frame of CDC's National Immunization Survey (NIS), following NIS random-digit dialed telephone survey; surveys vary, based on need of sponsors. Tracks and monitors health and well-being of children and adults in 50 states, District of Columbia, and 27 urban areas. Contacts more than 1 million households annually.
The National Health and Nutrition Examination Survey (NHANES)	CDC/National Center for Health Statistics	Nationally representative survey of 5,000 persons annually, combining interviews and physical exams; focus on different population groups or health topics. Used to determine prevalence of chronic conditions, risk factors for disease, nutritional status; helps to develop public health policy, direct and design health programs and services, and expand health knowledge.

The AFHSC maintains, promotes, and enhances the health of military and military-associated populations through development, refinement, and improvement of surveillance methods; coordinates a global program of militarily relevant infectious disease surveillance.

Defense Medical Surveillance System (DMSS)

In 1997, The Army Medical Surveillance System transitioned to the Defense Medical Surveillance System (DMSS). This is the primary tool used by AFHSC for all its public health surveillance. It combines data from inpatient, outpatient, and purchase care databases maintained by TRICARE Management Activity and contains personnel data from Defense Manpower Data Center and health assessments completed by SMs. The DMSS contains data from three main sources: Standard Ambulatory Record Data (SADR) and Comprehensive Ambulatory Professional Encounter Record (CAPER); Standard Inpatient Data Records (SIDR); and TRICARE Encounter Data (TED)/Health Care Service Record (HCSR). DMSS data are integrated in a continuously expanding longitudinal surveillance data base for all persons who have served since 1990 and facilitate the efficient analyses of morbidity among SMs.

Theater Medical Data Store (TMDS)

The TMDS receives data from various military and civilian systems, which allows the following: view clinical information; view, track, and manage ill or injured patients through

continuum of care; access data on critically injured patients before they arrive a next point of care; access to deployment-specific medical data; access to blood inventory management activity; and, view pre-deployment health information.

Blast Tracker Program (BTP)

The Army National Guard designed the Blast Tracker Program (BTP) as a secure data base accessible to all service branches via defense link website. It will be incorporated into the Combined Information Data Network Exchange of U.S. Central Command data system. The goal is to capture blast and related events and identifies persons in proximity to blasts. Units and individual persons can receive reports and previously deployed units can add past exposure information.

VA

The following systems are implemented by the Veterans Health Administration (VHA) to identify veterans receiving health care within VA who have a possible TBI.

VA TBI Screening and Evaluation Program

The TBI Screening and Evaluation Program is a web-based tracking application that began in 2007 to capture information on veterans who screen positive for mild TBI using a TBI Clinical Reminder tracking system. The system was designed to improve screening for veterans of Operation Enduring Freedom (OEF) and Operation Iraqi Freedom (OIF) for mild TBI. The program provides information to confirm diagnosis and provide treatment.

VA TBI Health Registry

The TBI Health Registry is a secure web-based portal for VA users to evaluate data, develop policies, assess resource demands, determine incidence/prevalence of TBI and evaluate treatment and outcomes. The system provides prospective longitudinal health surveillance, epidemiologic, and health-care quality analysis for OEF/OIF veterans.

Challenges/Limitations

The identification of veterans who had a military service-related TBI in the immediate or remote past in the civilian systems poses many medical, epidemiologic, methodologic, and administrative challenges. Collecting data, standardizing collection methods, and sharing data among partner agencies is a critical component of an overall plan to improve the outcome of TBI injuries. Furthermore, these data will support future efforts related to the implementation of prevention measures.

Veterans with moderate or severe military service-related TBIs have the potential to be counted easily because their injuries are often self-evident. They frequently have clear clinical signs of brain injury or with imaging results (CT and/or MRI) that are abnormal. Similar to civilians, veterans with less severe TBIs might be more difficult to identify if their signs and symptoms were not evaluated immediately after the injury, not recorded (*National Center for*

Injury Prevention and Control [NCIPC], 2003), or not diagnosed (Andary et al., 1997; Chambers, Cohen, Hemminger, Prall, and Nichols, 1996). Long-term dysfunction might be related to multiple events of mild TBI, making the number of exposures as important as the severity of any single exposure. Accurate measures of the accumulated number of blast exposures add further complexity to accurate data gathering. Moreover, diagnosing TBIs that occurred years previously, such as during the First Gulf War, might be difficult because of substantial memory loss and inability to recall the initial diagnosis, external causes, or risk factors (Jekel, Katz and Elmore, 2001; Paterson and Scott-Findlay, 2002). Survivors also might have comorbidities, such as PTSD, that might mimic or overlap with the signs and symptoms of TBI (Glaesser, Neuner, Lutgehetmann, Schmidt, and Elbert, 2004; McMillan et al., 2001; Schneiderman, Braver, and Kang, 2008). In other instances, health-care providers might not be able to detect or diagnose (Jekel, 2001) TBIs and/or determine causative factors, especially if they are mild (Andary et al., 1997; Chambers et al., 1996). Other medical concerns include malingering (Halligan, Bass, and Oakley, 2003; Sweet et al., 2000; Bianchini Curtis, and Greve, 2006) or the inability of the civilian provider to access military medical records documenting the injury event, diagnosis and risk factors.

Identifying veterans who had a military service-related TBI since the beginning of the First Gulf War in the civilian system requires data sharing among interested parties. Such sharing of data might be particularly useful for identifying those veterans who are subsequently receiving care in the civilian health-care system. However, this poses administrative challenges, including the Health Insurance Portability and Accountability Act of 1995 (HIPAA) Privacy Rule (United States Department of Health and Human Services, 2009) that regulates uses and disclosures of “protected health information” (PHI) by covered entities (45 CFR 164). The HIPAA Privacy Rule defines covered entities as health-care providers, health plans, and health-care clearinghouses (45 CFR 160.103 (B)(3)). Examples of PHI include information that identifies or can be used to identify a person who is related to any physical or mental health condition, or treatment, or payment for treatment of a person by covered entities.

The HIPAA Privacy Rule permits the disclosure of PHI without the authorization of the individual for specified purposes including disclosures required by law and disclosures to public health authorities who are authorized to collect it. HIPAA generally requires the disclosure of the minimum amount of information necessary to achieve the intended purpose (45 CFR 162.502 (b)). CDC and state health departments, as public health agencies with public health authority, may obtain protected TBI-related health information for public health purposes (under 45 CFR 164.512(b)(2)) from VA and DoD to identify the target population of this report in the civilian system. Various applicable laws regulate the disclosure of identifiable information from CDC and state health departments (e.g., the Privacy Act, HIPAA Privacy Rule, state laws). Development and dissemination of veterans’ TBI-related information in the civilian health-care and public health systems will require high levels of cooperation and collaboration among various federal (CDC, NIH, DoD, and VA), state, local entities, and other stakeholders. Despite these hurdles, the Federal TBI Common Data Elements project is developing standards so that TBI in persons formerly in the military is effectively measured and data shared among interested parties while maintaining appropriate privacy protections. The ongoing activities of this interagency group can go a long way towards further strengthening collaboration and data sharing among organizations responsible

for conducting, monitoring, and evaluating current civilian and military TBI- related surveillance systems.

EPIDEMIOLOGY

Epidemiology is the study of the distribution and determinants of health-related states or events in specified populations, and the application of this study to the control of health problems (*Last, 1988*).

The epidemiology of a condition, like TBI, can be characterized using data collected via surveillance systems as described in the surveillance section above. Injury surveillance data are useful for several reasons. Even the simplest surveillance programs are designed to identify as many persons as possible who have a particular injury or disease. Other programs, like the CDC Core Violence and Injury Prevention Program surveillance system (*Marr and Coronado, 2004*), might collect additional data about selected demographic and clinical characteristics of the injured population, cause of injury, alcohol use, and use of protective devices, such as seat belts or motorcycle helmets.

Although surveillance systems typically do not collect data at the same level of detail as research studies, they provide more current data than research data. Furthermore, they can generate data on an ongoing basis, which is useful for studying, for example, trends or the efficacy of preventive interventions (*Coronado et al., 2009*). Obtaining more detailed epidemiologic data requires in-depth and time- consuming studies of specifically defined populations (*Coronado et al., 2009*). In most cases, researchers find it feasible to collect the necessary amount of details from samples of persons drawn from a population of interest rather than study the entire population (*Coronado et al., 2009*). These limitations contribute to the difficulty of extrapolating results from detailed studies to surveillance data. However, data from both approaches are necessary to understand the magnitude and effects of injuries and diseases.

Incidence: Traumatic Brain Injury

Incidence indicates the number of new cases that occur over time. It is usually expressed as a percentage of persons who will be affected during a year, or as a rate calculated as the number of persons who develop the condition during a period divided by the number of person-years at risk.

From 2000 through 2011, a total of 235,046 service members (SMs) (4.2%) of the total 5,603,720 who served in all components of the Army, Air Force, Navy, and Marine Corps were diagnosed with a TBI. Most of these SMs with a TBI (76.7%) had a mild TBI (Figure 1). Less than 3% of SMs with a TBI had severe and penetrating TBIs (Figure 1).

The overall rate of TBI among active duty service members more than doubled from 720.3 per 100,000 SMs to 1,811.4 per 100,000 SMs from 2000 to 2011 (Table 6 and Figure 2). The TBI rate increased dramatically from 2006 to 2008 followed by slight increases in 2010 and 2011. This may reflect an actual increase in TBI, but may also reflect an increased number of SMs deployed along with increased awareness of the need to seek care and

improved recognition and diagnosis. Overall TBI rates increased in every active-duty service branch from 2000 through 2011 (Figure 3). The largest increases were among active-duty Army and Marine Corps members. The rate of TBI in the active-duty Army was 3.3 times higher in 2011 than in 2000 (2,717.9 versus 815.6 per 100,000 service members). The TBI rate among active-duty Marine Corps personnel in 2011 was 2.4 times higher than in 2000 (2,286.3 versus 959.8 per 100,000 SMs).

Source: Defense and Veterans Brain Injury Center.

Figure 1. Percentage of U.S. military service members diagnosed with a TBI, by TBI severity, 2000-2011 (N = 235,046).

The mild TBI rate among active-duty service members increased from 2000 through 2011 (Table 6 and Figure 4). The increase in the rate of mild TBIs accounted for most of the increase in the overall TBI rate in the active-duty military population. The rate of moderate TBIs in this population decreased from 2000 through 2005 and then increased in 2006 and 2007, followed by a decrease in 2008 and then increased each year through 2011 (Table 6 and Figure 4). The rates of penetrating and severe TBIs among active-duty service members increased dramatically from 2006 through 2009 (Table 6 and Figure 5). However, these rates decreased substantially after 2009 (Table 6 and Figure 5). In 2010 and 2011, the rate of penetrating TBIs among active-duty service members decreased 43.9%. During those 2 years, the rate of severe TBIs decreased 33.4%; this decrease is likely a function of multiple factors including fewer people deployed and improvements to both vehicles and personal protective equipment.

The incidence of blast-induced TBI in U.S. civilian populations is low, with a report of 0.2% of TBI cases in a major urban trauma center (Bochicchio *et al.*, 2008); however, civilian blast injuries are becoming an increasing problem worldwide (Summers *et al.*, 2009). Data for TBI in the civilian population from 1995 to 2009 show that the rate for emergency department visits increased significantly from 434.1 per 100,000 population in 1995 to 686.0 per 100,000 in 2009. During the late 1990s, the rate of TBI hospitalizations decreased significantly from 95.5 per 100,000 population in 1995 to 77.9 per 100,000 in 2000 but then the rate increased over subsequent years and the rate for 2009 was similar to that reported in 1995. Deaths in which a TBI was listed either as an isolated injury or in conjunction with

other injuries decreased significantly from 19.9 per 100,000 in 1995 to 16.6 per 100,000 in 2009 (Coronado et al., 2012).

Table 6. Estimated annual rates* of TBI among active-duty U.S. military service members by TBI severity, 2000-2011

Year	Penetrating	Severe	Moderate	Mild	Not Classifiable†	Overall
2000	17.9	11.6	274.8	413.7	2.3	720.3
2001	19.4	12.6	234.4	506.0	2.3	774.7
2002	13.9	9.2	192.3	553.7	2.4	771.5
2003	16.0	10.4	150.1	563.5	1.8	741.8
2004	17.1	9.0	128.5	614.7	2.1	771.4
2005	13.9	9.8	108.3	581.5	2.3	715.9
2006	19.7	11.1	145.3	835.7	3.4	1015.1
2007	23.9	13.3	216.9	1087.5	13.8	1355.3
2008	27.7	15.1	193.6	1289.5	169.7	1695.6
2009	28.2	18.5	205.0	1279.8	126.6	1658.1
2010	17.1	13.3	236.8	1405.6	90.7	1763.6
2011	15.8	12.3	239.4	1429.1	114.8	1811.4

* Incidence Rates per 100,000 service members.

† Changes were made to the DoD TBI case definition in 2008 to include codes that do not provide information about the severity of the TBI.

Although additional research is required to understand the specific causes, a number of factors may have contributed to the significant increase in the rate of TBI-related emergency department visits including the increased awareness of head injury through education campaigns (for example, CDC's *Heads Up: Concussion* campaign), the efforts of various sports organizations to reduce TBI among athletes, and the media attention given to TBI among military service members fighting in Iraq and Afghanistan. In addition, a number of states have passed legislation to reduce TBI in youth sports, further raising awareness of the importance of addressing these kinds of injuries among coaches, athletic trainers, parents, and youth. While a number of factors likely contributed to the decline in TBI-related deaths, the largest single contributor is the reduction in the number of transportation related deaths (Coronado et al, 2012).

Prevalence: Traumatic Brain Injury

Prevalence is the number of all new and old cases of a disease or occurrences of an event (in this case TBI) during a particular period (*Mosby 2009*).

Active Duty Military Personnel

Determining the prevalence of TBI in the transient military population remains challenging as it might not allow accounting for all those who are living with the consequences of this condition. Other challenges stem from the use of multiple databases and electronic medical records that lead to duplication of cases or inability to locate records and inconsistencies in coding that might contribute to inappropriate symptom attribution.

Another concern that can affect reporting prevalent cases is the lack of chronic TBI codes. Commonly, SMs might be seen and treated for persistent headaches following TBI. The primary diagnostic code is captured as headache. Unless a history of TBI code is also used, this person might not be captured in reporting. The DoD, CDC, VA, and other federal agencies collaborated to revise the ICD-9 codes that most accurately reflect TBI. These revisions that are already in use incorporated consideration of co-morbid conditions and were publicly reviewed, discussed, and adapted by all partners. The addition of cognitive-behavior codes is important because many of the symptoms of mild TBI overlap with psychological comorbidities, in particular PTSD.

Figure 5. Estimated annual incidence rates of penetrating and severe TBIs among active-duty U.S. military service members, 2000–2011.

Inconsistencies in coding also might affect reporting. To overcome these problems, educational activities are underway to ensure that providers and medical coders consistently use recommended codes that will enhance incidence and prevalence detection. Guidance documents have been developed to assist in improving documentation (*TRICARE 2010*; *Defense Centers of Excellence, 2010*).

To better estimate the prevalence of TBI in the military, MHS requires continuing the practice of conducting pre-deployment screening to have baseline measures; after a possible TBI, screening all SMs as soon as possible; training all medical personnel in the detection of TBI and coding methods for TBIs; improving and maintaining better medical record keeping

and reporting; and expediting the standardization of the multiple and disparate databases in the military. Efforts have been initiated to coordinate databases within the DoD and other federal agencies as mandated by the National Defense Authorization Act (NDAA).

Table 7. Numbers of OEF/OIF Veterans reported with ICD-9-CM codes indicative of TBI diagnosis or a selected TBI outcome or other type of head injury commonly associated with TBI who were evaluated or treated in the VA health-care system from October 2001 through December 2011

Diagnosis/Health Outcomes	Number ¹ of Veterans (N = 59,218)
Postconcussion syndrome	12,367
Fracture of skull ²	113
Fracture of base of skull ²	113
Fracture of face bones ²	3,237
Other and unqualified skull fracture ²	90
Multiple fractures involving skull or face with other bones ²	209
Concussion ³	36,412
Cerebral laceration and contusion ³	392
Subarachnoid, subdural, and extradural hemorrhage following injury ³	243
Other and unspecified intracranial hemorrhage following injury ³	62
Intracranial injury of other and unspecified nature ³	18,509
Injury to optic nerve and pathways ²	257

Source: Epidemiology Program, Post Deployment Health Group, Office of Public Health, Veterans Health Administration, Department of Veterans Affairs, March 2012.

¹The sum of the number of veterans corresponding to each ICD-9-CM code is more than 59,218 because a patient might have more than one ICD-9-CM code.

²ICD-9-CM codes that are commonly associated with TBI.

³ICD-9-CM codes with specific TBI diagnoses.

The majority of TBIs are mild (approximately 80%; *Thurman, Alverson, Dunn, Guerrero, Sniezek, 1999; Defense and Veterans Brain Injury Center, unpublished data*) and less likely to yield chronic symptoms. If mild TBI-related symptoms are present, they are often non-specific headaches, dizziness, or cognitive or neuropsychiatric difficulties. According to current coding guidelines, chronic symptoms, such as headache, are recorded but often without information necessary to determine whether and how they may be attributed to a prior TBI. Therefore, the prevalence of mild TBI is difficult to ascertain. SMs who have sustained a moderate, severe, or penetrating TBI and who are represented in the TBI database are more likely to have disability linked to their TBI. However, with the exception of post-traumatic epilepsy, no process is in place for determining and recording long-term consequences.

Veteran Population

The overall U.S. veteran population is diverse and includes those who served during various eras, including WWII, the Korean conflict, the Vietnam War, the First Gulf War, OEF/OIF, and other conflicts and operations. The number of women veterans has steadily increased; beginning in the First Gulf War, women have played an increasingly important role in the U.S. military. Estimating the TBI prevalence in veteran population should optimally consider services provided by both the VA health-care system and civilian medical facilities

outside of that system. Prevalence among OEF/OIF veterans seen by VA is defined by data from VA's Inpatient (PTF) and Outpatient (OPC) treatment records data and is presented in Table 7.

Epidemiologic studies of the long-term consequences of TBI, including those that focused on veterans who served during WWII, the Korean conflict, and the Vietnam War have been reviewed by the Institute of Medicine (IOM 2009). Many of the early studies of TBI reviewed by IOM focused on moderate or severe TBI or pre-date contemporary improvements in assessment, treatment, and rehabilitation, highlighting the ongoing need for additional research.

Several factors have contributed to current interest in understanding the epidemiology, early detection, treatment, and rehabilitation of not only moderate and severe TBI but also mild TBI. This includes increased use by enemy forces of improvised explosive devices (IEDs) and rocket propelled grenades (RPGs); increased survival of military service men and women who are critically injured on the battlefield; and recognition of the potential for overlap between mild TBI and PTSD. In the last decade studies within the U.S. military and VA systems have addressed the long-term consequences of military service-related TBI. Of these studies, most address the consequences of military service-related mild TBI (*Hoge et al., 2008; Schneiderman et al., 2008; Taber and Hurley 2009; Rona et al., 2012*).

The National Defense Authorization Act of Fiscal Year 2008 (Public Law 110-181, Section 1704 (d) requires the VA Secretary to establish and maintain a TBI Veterans Health Registry (VHR). The registry must include information about each person who served as a member of the Armed Forces in OEF/OIF who exhibits symptoms associated with TBI and who applies for services or files a disability claim. Section 1704 also stipulates that the VA shall collaborate with facilities that conduct research on rehabilitation for persons with TBI, facilities that receive grants for such research from the National Institute on Disability and Rehabilitation Research (NIDRR), DVBIC, and other relevant programs of the Federal government, including the Defense Centers of Excellence.

Pursuant to this statutory requirement, VA sought an interagency agreement with NIDRR through which VA can draw upon the expertise of NIDRR's TBI Model Systems (TBIMS) program—the largest longitudinal database for TBI in the country. With NIDRR's assistance, VA is working to develop a TBI VHR housed on secure web-based portal at the TBIMS National Data and Statistical Center in Denver, Colorado. The portal will be accessible to authorized VA users and developed in compliance with VA data security regulations, HIPAA, and Privacy Act considerations. A custom-built web portal will enable authorized VA users to access data to support policy development and evaluation; assess resource usage and health-care needs; determine incidence and prevalence of TBI among OEF/OIF veterans; and evaluate course of treatment and outcomes.

Characterizing the prevalence and long-term consequences of military service-related TBI in the civilian system will require even greater manpower and economic resources to ensure that appropriate linkages are made between the military, VA, and civilian health care systems. There is also an absence of fully valid and reliable screening instruments to diagnose TBI, especially cases of mild TBI, and the co- occurrence of cases of PTSD and TBI that are not correctly classified. Moreover, the natural history of combat-related TBI, especially its long-term consequences, has not yet been fully explained (*Ramchand et al., 2008*).

Because the VA system provides medical care to a subset of all eligible veterans, conducting studies of the prevalence of military service-related TBI will likely require the use

of civilian databases, for example, the TBIMS or the Framingham Study. The Framingham Study has been conducting research on neurological disorders for decades. In 1997, for example, it began a post-mortem Brain Tissue Donation Program that has enrolled more than 600 participants and analyzed approximately 100 brains—yielding substantial information on genetics, the environment, the aging process, stroke, Alzheimer's disease, Parkinson's disease, or other neurological illness. Because the program can also document the extent of a disease, military service-related TBI and civilian TBI could also be studied.

Civilian Population

Certain challenges related to TBI prevalence in military-associated cases also affect civilian populations. An estimated 3.2 million Americans are living with long-term consequences from TBI (Zaloshnja, Miller, Langlois, and Selassie, 2008). This estimate reflects the use of updated methodology and is based on the results of statistical modeling and analysis of 2005 TBI hospitalization incidence data from Maryland, Vermont, and New Jersey. A previous CDC estimate indicated that approximately 2% (approximately 5 million) of the U.S. population live with the long-term consequences of TBI (CDC, 1999). These estimates, likely underestimate the prevalence of TBI-related disability as they do not include persons with TBI who were treated and released from emergency departments or other health-care settings, those who were treated in a DoD or VA facility, or who did not seek treatment. With current resources and limitations in surveillance methodology, the prevalence of TBI-related impairment and disability in the United States cannot be measured with confidence (Coronado et al., 2009).

Interview surveys that attempt to link history of TBI to a disability are prone to underreporting, mainly because of poor or no recall of past injuries (Walker, Logan, Leukefeld, and Stevenson, 2004). Population-based prospective cohort studies of persons recently diagnosed with an acute TBI might be more promising. Using this method, two studies examined the occurrence of TBI-related disability in representative samples of persons followed 1 or more years after hospitalization for TBI (Whiteneck et al., 2004; Pickelsimer et al., 2007). Since information on annual disability (Selassie et al., 2008) does not account for the cumulative prevalence of TBI, statistical methods must be applied to estimate such figures (Zaloshnja et al., 2008). The true prevalence of military and civilian TBI and TBI-related disability in the general U.S. population will remain elusive without continued investment in sound, long-term, representative follow-up studies or adding questions into existing national surveys, such as, NHIS, NHANES, and SLAITS.

The Economic Costs of TBI

The economic costs of TBI are difficult to estimate in both the military and civilian populations. Some of the reasons include 1) uncertainty about which outcomes can be attributed specifically to TBI, 2) variability in the types of TBI-related outcomes, 3) inability to measure the precision of cost estimates, and 4) limited resources (including data available for research) to conduct more complex and long-term economic studies. Some estimates are more straightforward whereas others can only be derived using a large number of

assumptions and complicated econometric and statistical methods that distance the estimates from actual cost data (*Coronado et al., 2009*).

Because of these difficulties, few attempts to estimate the costs of TBI have been undertaken, especially those costs faced by society as a whole. One recent study estimated the annual economic burden of TBI in the United States in year 2000, including direct medical and rehabilitation costs and societal costs, to be \$60 billion (*Finkelstein, Corso, and Miller, 2006*). The few studies that have attempted to estimate the cost of TBI injury among military SMs have had major limitations such as including only hospitalized cases of TBI and studies with small sample sizes. Despite these limitations, available data suggest that the total costs might be substantial (*Ommaya, Ommaya, Dannenberg, and Salazar, 1996; Wallsten and Kosec, 2005; Eibner, Ringel, Kilmer, Pacula, and Diaz, 2008*).

Certain studies have attempted to estimate the costs of TBIs that have resulted from OEF/OIF. One study estimated that the total lifetime cost of severe TBIs sustained in OIF through August 2005 to be \$16 billion (*Wallsten and Kosec, 2005*), but it has two limitations that must be considered. First, the authors estimated that 20% of all SMs wounded in OIF had a severe TBI, which is high when compared with DoD data. DoD TBI surveillance data indicate that only 1% of all SMs with a TBI during that time sustained a severe TBI (*Defense and Veterans Brain Injury Center, unpublished data*). Furthermore, the estimated proportion was obtained from a newspaper article rather than actual surveillance data. The second limitation was that the lifetime cost of severe TBI was based on numerous assumptions and estimated costs that might not be applicable to SMs with TBI. For example, the data used to estimate lifetime-treatment costs was derived from civilian sources and might not be applicable to the DoD and VA health systems. A 1996 study of costs for acute treatment of TBI among SMs and their beneficiaries suggests that costs in military hospitals might be lower than costs in private hospitals (*Ommaya, 1996*). Furthermore, a highly variable and controversial cost, known as the value of a statistical life (VSL), was used to estimate other aspects of the lifetime cost of severe TBI, such as lost wages. The VSL is the value that a person places on a marginal change in their likelihood of death; it is estimated by looking at the risks that people are voluntarily willing to take and how much they must be paid for taking them (*Viscusi and Aldy, 2003*). A review of literature about VSL indicated that it can vary from \$4 million to \$9 million per life, depending on the assumptions made and methodology used to estimate it (*Viscusi and Aldy, 2003*).

In 2008 the RAND Corporation released a report estimating TBI costs resulting from OEF/OIF (*Eibner et al., 2008*). The report provided cost estimates for acute treatment and rehabilitation, mortality and suicide, and lost income. In the first year following injury, costs were estimated to be \$27,260 to \$32,760 per case for mild TBI and up to \$408,520 for those with moderate to severe injury. The estimated overall cost for acute treatment of deployment-related TBIs in the hospital in 2005 ranged from \$6.9 million to \$14.3 million. The estimated cost of inpatient rehabilitation was \$1.9 million and the estimated cost of outpatient rehabilitation ranged from \$377,000 to \$907,000. The estimated costs associated with mortality from deployment-related TBIs in 2005 ranged from \$67 million to \$89 million, unemployment associated with deployment-related TBI was \$13 million, and reduced wages associated with deployment-related TBI was \$1.2 million.

These estimates have the same serious limitations as those calculated by Wallsten and Kosec in 2005. Treatment cost estimates are derived from civilian cost data that might be different from costs incurred by military hospitals. In addition, estimated costs resulting from

the death of a SM are based on the VSL, which can vary substantially. Another serious limitation is that the estimated treatment cost per case of mild TBI in the RAND report is for SMs who required hospitalization. This estimate is likely too high for most SMs with a TBI because most persons with mild TBI only are not hospitalized. More problematic is the lack of evidence regarding the extent of long-term disability resulting from blast exposure and whether other major health effects such as neurodegenerative disorders might arise years later.

Table 8. Estimated median acute hospitalization cost per patient for military personnel hospitalized with TBI (in 2011 Dollars)

TBI Characteristics	Cost/Patient†	
	Military Hospital	Private Hospital
TBI with no LOC*	\$1,773	\$5,308
TBI with any LOC*	\$2,299	\$8,216
TBI with LOC of unknown duration	\$2,901	\$6,051
TBI with LOC >1 hour	\$8,237	\$22,744
TBI with other type of injury	\$10,245	\$10,991
TBI with other health condition	\$3,967	\$7,835

Source: Defense and Veterans Brain Injury Center.

† Costs presented in this table are medians of actual costs incurred by military hospitals and allowable expenses paid by the MHS to private hospitals in fiscal year 1992 (*Ommaya et al.1996*). These costs have been adjusted to 2011 dollars using the U.S. city average CPI for medical care (*US Bureau of Labor Statistics*). Military and private hospital cost estimates might not be directly comparable because of the different methods used to compute them. However, the military hospital costs include the clinic proportion of total facility expenses including construction, maintenance, staff wages, equipment, and supplies.

Using 1992 data, the Defense and Veterans Head Injury Program, now DVBIC, published estimates of TBI-related costs in the military (*Ommaya et al., 1996*). These costs were estimated from a study of 5,568 SMs and other beneficiaries of the MHS who were hospitalized for TBI in both military and private hospitals in FY 1992. The authors attempted to compare costs from both types of hospitals. Although outdated, these estimates are the only ones known to be published that were derived from actual costs incurred by the MHS. The overall estimated cost of TBI-related hospitalizations in the U.S. military medical system in 1992 was approximately \$42 million (*Ommaya, 1996*).

Current military per-patient hospitalization costs associated with TBI in the military can be estimated by adjusting Ommaya et al.'s estimates for inflation. This method has been used by others to update older cost estimates (*Thurman, 2001*). Table 8 presents Ommaya et al.'s per patient cost estimates adjusted to 2011 dollars. However, these estimates have limited reliability because the inflation factor used for adjustment was not just for hospitalizations, and included all types of health care. Furthermore, the inflation rate for TBI treatment costs might be different from treatment cost inflation for other conditions.

Estimating the Cost of TBI

The only way to obtain realistic estimates of TBI-related costs in the military is to perform a comprehensive long-term study that obtains actual cost data at the level of individual patients, based on specific TBI characteristics, treatments, comorbidities, health

consequences, rehabilitation needs and long-term disability. Such a study must follow injured SMs and veterans over a long period to collect accurate cost data for services they receive. It must also account for the effects of improvements in technology and treatment on costs to ensure compatibility of cost estimates from different periods. To obtain information about the economic consequences of TBI-related mortality, families of those SMs who died from TBIs also can provide insight. Without continued study of the outcomes of military service-related TBI, estimates of the total costs of TBI to society will continue to rely mostly on assumptions and complex economic modeling techniques that might result in estimates that are imprecise or unreliable.

PREVENTION

Preventing TBI

Many potential ways exist to prevent TBI and the poor outcomes that can result when TBIs are sustained. Improving outcomes from TBI includes pre-hospital care and faster transport to medical centers. Early detection with better diagnostic tools also can lead to better outcomes when paired with timely interventions. Reducing risk of injury and preventing further damage after initial injury are essential to ensuring improved outcomes. Protective gear, including helmets, can prevent or reduce the severity of TBI. Helmet use is recommended in many sports and combat situations, and improved helmets with stronger and lighter weight ballistic materials for the helmet's outer shell as well as new helmet pads to provide greater blunt impact protection are under development as part of a developmental program known as the Soldier Protection System (SPS).

Source: Faul M, Xu L, Wald MM, Coronado VG, 2010.

Figure 6. Fatal and nonfatal traumatic brain injuries either occurring alone or in conjunction with other injuries by mechanism - US, 2002-2006.

The goal of SPS is to do development and testing during FY13 and FY14 with the intention of beginning production in FY15. The use of seatbelts in motor vehicles is required, as are motorcycle helmets for SMs in the non-deployed setting. Although not yet well understood, chest protection also seems to reduce blast TBI severity in rats, possibly by preventing systemic changes in blood pressure (*Long et al., 2009*). Enhanced forms of hard armor ballistic plates, improved outer tactical vests, pelvic protection systems, ballistic eyewear, and limited numbers of face shields and lower mandible protectors have already been fielded and will be further enhanced through the SPS. All of these improvements to personal protective gear are crucial advances for SMs moving outside of the forward operating bases and especially when dismounted from a vehicle. In addition, improved vehicle armor has also been instituted over the last several years to mitigate blast effects on vehicle occupants. Improvements in protective eyewear not only minimize fragment penetration to the eyes but also penetration to the brain.

Among veterans and SMs returning to the United States who are no longer at risk for deployment-related injuries, the prevention of TBI is similar to the civilian population (Figure 6). The majority of TBIs, either occurring alone or in conjunction to other injuries, are caused by several factors (e.g., falls, motor vehicle traffic crashes, and striking or being struck by an object or person, or acts of violence against oneself and others) (*Faul et al., 2010*).

Preventing TBI Associated with Motor Vehicle Traffic Crashes

Motor vehicle crashes and resulting injuries are a serious public health problem among civilian and military populations. Implementing prevention strategies to decrease the occurrence of these incidents is a public health priority.

Mortality rates from severe TBI in motor vehicle crashes (a leading cause of severe TBI in civilians and SMs) have declined since the 1970's, but remain unacceptably high. Programs and policies that encourage improvements in vehicle design, the road environment, and reductions in risky behaviors such as speeding, alcohol-impaired and distracted driving can reduce the risk of crashes. Activities that encourage improvements in occupant protection such as appropriate seat belt use and air bags can reduce the risk of injury in the event of a crash. Programs and policies to protect motorcyclists from injury include those that promote the use of helmets. Risks to pedestrians can be reduced through various measures that include vehicle, environmental and behavioral factors. (*NHTSA, 2011; Elvik, Høy, Vaa, and Sørensen, 2009*)

Preventing TBI Associated with Falls

Causes of falls vary, whether they occur as a result of falls among adults who might slip in their homes or teenagers who fall while engaging in athletic activities. Among older adults, fall-related injuries can be reduced by programs supporting regular weight-bearing and balance exercises; over the counter and prescription medication review to reduce use of those causing dizziness or drowsiness; annual eye exams to optimize vision; and home modifications when prescribed by an occupational therapist (e.g., reducing tripping hazards,

adding grab bars inside and outside the tub or shower and next to the toilet, adding stair railings and improving lighting) (Stevens, 2010; Gillespie *et.al.*, 2009). Injuries from falls among working-aged adults are most commonly experienced on the same level, on/from stairs or steps, or from a height such as on ladders or scaffolds; fall injuries during work are similar to those that are non-work related, suggesting that programs and policies successful in one arena might be applicable to others (Smith, Sorock, Wellman, Courtney, and Pransky, 2006).

Preventing TBI Caused by Striking or Being Struck

Struck by/against events are those in which a person was struck and unintentionally injured by another person or object (e.g., falling debris, a ball in sports) or a person struck against an object, such as a person struck against a wall or a collision between two or more people (Rutland-Brown *et. al.*, 2006). Many sports-related TBIs are included in this category. Sports and recreation-related TBIs can be prevented by programs and policies encouraging appropriate use of safety gear (such as helmets), environmental changes (such as padding goal posts and padding or removing other obstacles), strict officiating and enforcement of rules and sportsmanship, and examination of effects of select rule changes (Gilchrist, Saluja, and Marshall, 2007).

Rest before returning to play or work after even mild TBI is equally important. Re-injury leading to sudden death (second-impact syndrome) has been reported in some athletes who returned to sports after symptomatic concussions (Franklin, 2012). As described in the In-theater Screening section under Diagnosis, the military has implemented required rest periods following TBI.

Preventing TBI Associated with Intentional Injury

In addition to assaults, TBIs can result from self-directed violence, which is included as “other/unknown” in Figure 6. Interpersonal conflicts, relationship problems, and alcohol/drug use are common circumstances preceding homicides and suicides (Karch, Logan, and Patel, 2011). Suicide and violence- prevention strategies can reduce the risk of TBI by enhancing social problem solving and coping skills, improving access and reducing barriers to appropriate mental health care, and providing support and services to those struggling with multiple life stresses, including financial, substance abuse, and family violence-related challenges (Lubell and Vetter, 2006; Goldsmith, Pellmar, Kleinman, and Bunney, 2002; CSPV, 2012). In addition to individual and family-level factors, suicide and violence prevention strategies also need to address community-level factors such as norms about violence and help-seeking, access to education and employment opportunities, and the level of connectedness or social bonds among people (CDC, 2010).

Prevention of Secondary Brain Injury

Improved Emergency Medical Services (EMS) or pre-hospital care has substantially improved outcomes from TBI. In the prevention of secondary brain injury, pre-hospital care focuses on keeping airways open, maintaining blood and oxygen flow to the brain, and controlling blood pressure and hemorrhage, which can all improve survival and reduce long-term damage. Implementation of other types of early interventions to prevent secondary damage (e.g., hypothermia and administering osmotic agents) might depend on the situation, nearby infrastructure, and availability of experienced emergency teams (*Boer et al, 2012*).

Biomarkers for diagnosis also have the potential to improve early intervention and prevention of secondary injury. Research to identify TBI biomarkers is ongoing (*Schiff, 2012; Papa, 2012*). Some gene variants might have positive or negative effects on TBI outcomes (*Dardiotis et al., 2010; Miller et al., 2010; Al Nimer et al., 2012; Darrah et al., 2012*).

RECOMMENDATIONS

CDC, NIH, DoD and VA acknowledge that the military service-related TBI cases will be difficult to identify in civilian systems because several of these cases occurred in the past (e.g., during the early years of OIF). However, the majority of the incident and prevalent cases of military service-related TBI can be identified through TBI screening and reporting conducted by DoD and VA. Identifying cases of TBI not diagnosed while in service or by the VA system, although more difficult, might be possible by conducting surveys on veteran status; by educating health-care providers to ask their patients with TBI-related signs and symptoms about previous military service and risk factors, and to use, when appropriate, the terrorism and war-related ICD-9-CM external cause of injury (E) codes.

To accomplish the mandates of the *TBI Act of 2008* and to address identified public health concerns, CDC, NIH, DoD, and VA produced general recommendations applicable to all federal agencies and departments. In addition, recommendations specific to each agency and department might be useful for guiding their interactions with stakeholders. Underlying these recommendations is a commitment to using data sources that are accessible, valid, and reliable.

General Recommendations

CDC, NIH, DoD, and VA concur on the following key recommendations:

- **STRENGTHEN COLLABORATION:** Continue to foster and strengthen collaboration related to identifying military service-related TBI among current military SMs and veterans, including those who do not seek care from the military or VA health-care systems. Improving data collection and sources will be emphasized.
- **UTILIZE STANDARD DEFINITIONS:** Improve reporting through federal agencies that use and promote standard clinical and surveillance definitions and

severity classification of TBI among U.S. military and civilian health-care providers and researchers.

- **ENHANCE CODING AND CLASSIFICATION:** Continue to foster and strengthen collaboration with each other and other relevant organizations on coding and classification of TBI. All four participating agencies should continue to meet with professional, academic, health care, and coding organizations to discuss improvements in ICD-10-CM, including the classification of TBI and concussion and differentiation of self-limited and persistent symptoms. Revise the intracranial injury code set in ICD-10-CM to improve the accuracy of disease coding consistent with accepted case definitions before ICD-10-CM implementation on October 1, 2014.
- **IMPROVE DISSEMINATION:** Promote dissemination of information by federal agencies to non-VA facilities regarding TBI services available through the VA health-care system since 2007, including baseline screening and follow-up assessment and evaluation.
- **BUILD EVIDENCE BASE:** Continue research on the neurological consequences of blast events and TBI among SMs and veterans; the research should include 1) systematic neuropathological study in blast-exposed SM's and veterans who have died; 2) correlation of neuropathological and brain imaging findings; 3) prospective investigation of whether blast exposure increases risk for subsequent cognitive decline and neurodegenerative diseases such as chronic traumatic encephalopathy, Alzheimer's, Parkinson's and amyotrophic lateral sclerosis.

Recommendations to Improve TBI Diagnosis and Treatment

Military Health System

Development and validation of helmet-mounted sensor systems (HMSS). The Vice Chief of Staff of the Army (VCSA) directed that soldier combat helmets be fitted with electronic sensors that can record helmet response to dynamic events (blunt impacts, ballistic impacts, and/or exposure to blast events). Sensors that could be able to predict when someone has reached a threshold for exposures are under development (*McAllister et al., 2012; Broglio, Surma, and Ashton-Miller, 2012*). Development of a signal library of carefully controlled blunt, ballistic, and blast signatures will allow indirect identification of mechanical insults (exposure) of HMSS signals from the field. This will allow the development of an injury assessment tool, as the first approximation of a dose-response curve. Expanding the use of these sensors to the USMC and others with these types of exposures will be based on the efficacy of the Army's initial use of them.

Development of therapeutics to improve the outcome of mild, moderate, and severe TBI. Despite advances in basic and clinical research and neurological intensive care in recent years, and despite promising pre-clinical data, most of the clinical trials have failed to yield any significant improvement in TBI outcome. Nevertheless, DoD is currently exploring combination drug therapies, novel drugs, and small-volume resuscitation liquids (i.e., fluids administered to patients in relatively small amounts to restore and maintain adequate blood circulation following severe blood loss) for their ability to improve functional recovery from TBI.

Development of animal/computer model for TBI, most importantly for blast TBI.

No validated animal model exists for blast TBI. Development of a clinically and physiologically relevant model is critical for the successful validation of helmet-mounted sensors, SMS' protective armor, and for the evaluation of therapeutic interventions. Through a collaboration among Joint Improvised Explosive Device Defeat Organization (JIEDDO), DVBIC, and the Institute of Soldier Nanotechnology at MIT, the most advanced computer model of the brain and blast effects on the brain has been developed (*Moore et al., 2009*). Work to determine characteristic pathology of human blast injury is underway.

Identification of biomarker(s) to identify mild TBI/assay to discriminate between mild TBI and PTSD. Distinguishing between mild TBI and PTSD is complicated because of partial overlap in symptoms, including irritability, memory and concentration difficulties. The development of rapid, non-invasive, reliable testing is needed to discriminate between the subtle cognitive deficits of mild TBI and PTSD. Serum biomarkers such as S-100 protein show promise, although utility has been limited by its short half-life. Other biomarkers, including lactate dehydrogenase, neuron specific enolase, also might be useful but lack sensitivity and specificity (*Ingebrigtsen and Romner, 2002; Pike et al., 2004; Ringger et al., 2004; Pineda et al., 2007; Papa et al., 2010*). Preliminary results from ongoing serum biomarker studies are more promising. If these injuries could be detected objectively, quickly, and non-invasively, medical personnel would be able to begin early interventions.

VA Health System

The VA Office of Research and Development sponsored a State of the Art Conference in 2009 to identify research priorities for TBI. Representatives from DoD, NIH, DVBIC, and VA attended. A planning committee commissioned background papers for workgroup discussions. The papers examined topics such as the pathology of blast-related brain injury; diagnosis; comorbidities, including mental health issues and sensory deficits; brain imaging; care management; community reintegration; and, the role of veterans' families in TBI care. Six work groups focused on different aspects of TBI (i.e., basic science, neuroimaging, sensory deficits, comorbidities, rehabilitation and community reintegration, and care management) and then presented summaries of their findings and research recommendations for discussion with the entire group. An issue of the *Journal of Rehabilitation and Development* was dedicated to this meeting (Volume 46, Issue 6) and the research recommendations of the work groups were grouped into three main categories: (1) Diagnosing TBI (e.g., screening and imaging), (2) understanding short- and long-term effects of TBI (e.g., co-occurring conditions, severity, neurodegenerative disease), (3) understanding existing treatment approaches and developing new treatments (e.g., neurotrophins, neuroplasticity, case-management, community re-integration).

Civilian Health System

Although many opportunities exist to advance opportunities for TBI research and improve diagnosis and treatment in the civilian health system—that is, the organization of people, institutions, and resources to deliver health care services for the general population, a few strategic future directions for the field, with leadership from CDC, NIH, DoD, and the VA, include the following:

Developing a pathoanatomical classification system for TBI. During the past two decades much has been learned about TBI at a cellular and molecular level. Applying this knowledge to develop effective therapies for specific subtypes of injury, rather than for the entire constellation of injuries, is likely the key to developing successful interventions. Characterizing the pathophysiology and temporal evolution of these subtypes of injury would provide a foundation for identifying therapeutic targets and the window of opportunity for using them. It would provide the necessary scientific rationale for testing single and combined agents to hit these targets to attenuate injury or promote repair processes. A new classification system based on the pathoanatomy, rather than on the Glasgow Coma Scale also would inform chemical biomarker development and correlation of pathology with neuroimaging for these subtypes of injury. Surrogate markers would make it possible to identify people who have these subtypes of injury and also to monitor the biological effects of experimental interventions during clinical trials. Overall, breaking down the complex problem that TBI presents into smaller, more manageable parts should make it a more tractable problem.

Discovering the biological basis of mild TBI. This builds upon the previous recommendation because the milder injuries are often less complex than more severe injuries. Current research should be further enhanced to identify the biological mechanisms responsible for persistent deficits such as PCS and concurrent conditions including PTSD and to develop diagnostic tools for persons currently classified as having a mild TBI. Because a subset of persons described as having a mild TBI experience persistent disabilities, the term “mild” is often misleading.

Developing more effective and efficient approaches for preclinical drug development. Approximately 130 agents with proven preclinical efficacy for TBI are available, and more are under development and testing (*Marklund, Bakshi, Castelbuono, Conte, and McIntosh, 2006*). An efficient testing system for optimizing the dose and timing and for comparing effectiveness of interventions, alone and in combination, is needed to accelerate therapy development.

Facilitating data sharing. To date, much of the research on TBI has been small studies across agencies and centers, without definitively answering important research questions. A federal interagency project developed standardized terminology and a data dictionary for TBI to enable data sharing and secondary analysis and meta-analysis. In addition, the Federal Interagency TBI Research Informatics, a DoD and NIH collaboration, is available for aggregating and sharing data. Use across federal agencies is encouraged. Ongoing and new research on biomarkers would be accelerated by sharing data and supporting larger, multicenter projects to rapidly obtain greater numbers of samples and subjects. This is also true for advancing the development of neuroimaging and other diagnostic tools and biomarkers and for the validation of outcome measurement tools for clinical trials.

Coordinating and collaborating on clinical studies for TBI. A large, prospective observational comparative effectiveness research study is an efficient way to address some of the major gaps in knowledge regarding the validity of diagnostic tools and biomarkers and the effectiveness of various medical and surgical interventions for TBI. A coordinated and collaborative effort would enhance trial designs, increase the rate of subject enrollment and data collection, and optimize statistical analysis and data interpretation. Studies would be completed more quickly, and if successful, this collaborative approach would also facilitate implementation of these valid diagnostic tools, biomarkers, and proven interventions into clinical practice. TBI clinical studies should include subjects across the spectrum of injury

severity, across the lifespan, during acute and chronic stages of injury, and should evaluate pharmacologic and non-pharmacologic interventions.

Methodological Concerns and Research Priorities

Evidence indicates that continued research is needed to 1) determine the magnitude and socioeconomic and medical impact of military service-related TBI; 2) identify preventable and modifiable risk factors to reduce injury; 3) reduce impairment and disability; and 4) develop and evaluate evidence-based interventions.

CDC, NIH, DoD, and VA recommend that studies of the incidence and prevalence of military service-related TBI must include the following:

- Designed with clear and relevant research questions and methodology;
- Involve statistically representative populations;
- Allow determination of risk factors and the socioeconomic and demographic characteristics of these populations; and
- Allow characterization of the acute and long-term outcomes for TBI.

Such studies could assist in developing primary, secondary, or tertiary prevention programs, especially if modifiable risk factors are identified. Moreover, prevalence studies have the potential to identify gaps and guide resource allocation.

CDC, NIH, DoD, and VA also recommend continued evaluation and improvement of screening tools for TBI, especially tools used to identify milder forms of TBI. These studies are important to assess the incidence, prevalence, and long-term consequences of TBI, and the availability of and access to TBI-related support and rehabilitation services.

Finally, the four agencies also recognize that the recommendations in this report and all TBI-related management and treatment guidelines used by CDC, NIH, DoD, and VA need to be updated every 3 to 5 years to incorporate findings of epidemiologic, clinical, social, and behavioral research. The agencies are already working together through the Common Data Elements project and this provides one useful forum for regular reviews of important issues.

Morbidity and mortality associated with TBI affect civilian, military, and veteran populations. The leading causes of these injuries vary according to age and sex of injured persons. Therefore, these recommendations, prepared by the four participating agencies, will ensure that present practices in diagnosis of TBI and treatment for those persons affected by it will be sustained and improved. Additional progress to improve structural changes in defining TBI, improving surveillance systems, and recording epidemiologic data will assist in forming an achievable plan for the future.

Recommendations to Improve TBI Surveillance

Military Health System

To better estimate the incidence and prevalence of TBI in the MHS, DoD recommends:

- Screening all SMs as soon as possible following a possible TBI-causing event,
- Using the MACE or other appropriate screening tools; and
- Training all medical personnel (from theater through the VA system) in the detection and correct coding of TBI.
- Improving record keeping and standardizing multiple and disparate databases in the U.S. military using standardized common, streamlined questionnaires with variable complexity, depending on the level of care provided by the reporting medical facility (e.g., uncomplicated questionnaires for medics in theater to complex questionnaires for tertiary care facilities.) Coordination of databases has been initiated among DoD, VA, and NIDRR model systems.

Veterans Health System

Recommendations to better estimate the incidence and prevalence of TBI in the VA include:

- Continue screening all OEF/ OIF veterans upon contact with the VA health system;
- Training of all medical personnel in the detection of TBI and in the methods to correctly code for TBI; and,
- Timely and comprehensive follow-up evaluation of all veterans who screen positive for possible TBI.

Civilian Health System

Recommendations to improve surveillance of TBI in the civilian health system include:

- Expand surveillance activities by ensuring that TBI surveillance is part of comprehensive state injury surveillance systems,
- Continue to collaborate with DoD and VA to identify strategies for improving surveillance of TBI among veterans.

Methods for Detecting TBI Incidence and Prevalence

Military Health System

Key areas have been identified to improve measuring the incidence and prevalence of TBI in the military system, including case ascertainment; case documentation and reporting; follow-up; and, data dissemination. Specifically:

- Continue to use the established guidelines and strategies for identifying and treating TBI as described in this report; evaluate and update such guidelines every 3 years to reflect the advances in methods and technology.
- Produce portable data collection instruments to capture TBI data in the military, the VA, and civilian systems. These instruments should be specific to the level of care (e.g., a standard instrument to be used in theater only).

- Use TBI-specific diagnostic and external cause ICD-10 and ICD-9-CM codes to identify new cases (incidence) and history codes to ensure capturing prevalence data, recognizing the challenges of current coding and classification of TBI.
- Expand current care coordination and case management programs within DoD and VA to facilitate follow-up care and to document patients with persistent symptoms.
- Coordinate and exchange aggregated-level data (excluding personal identifiers) with CDC/NCIPC to produce a yearly report on TBI in the military by race/ethnicity, sex, age group, and risk factors. This report also should include information on the clinical characteristics, comorbidities, and concurrent injuries in persons with acute and chronic TBI.

VA Health System

Key areas have been identified to improve measuring the incidence and prevalence of TBI in the VA including:

- VA health-care system facilities should screen for TBI among eligible OEF/OIF veterans upon contact with the VA health system and further evaluate those who screen positive.
- Timely and comprehensive follow-up evaluation should be offered to veterans who screen positive for possible TBI.
- Medical personnel should be trained in TBI and in the methods to correctly code for TBI, recognizing the challenges with regard to current coding and classification of TBI.

Civilian Health System

Key areas have been identified to improve measuring the incidence and prevalence of TBI in the civilian health system including:

- Enhance capabilities to conduct surveillance at the state level; using national surveys, including public and private telephone and internet-based systems; and encouraging civilian and military health-care providers to document and report war and terrorism-related external cause-of-injury codes (E-codes).
- For all federally funded TBI research, use the newly recommended common operational clinical and surveillance definitions described earlier in this report, including all TBI-related ICD-10 and ICD-9-CM diagnostic, external cause of injury, terrorism, and war-related codes.
- Reporting incident cases of military service-related TBI while SMs are in the military. Collaborate with DoD, VA, and Defense Medical Surveillance System to share aggregated level data via CDC, and through peer and non-peer reviewed publications, periodicals, mass media, and books. Aggregate DoD TBI surveillance data is currently available at <http://www.dvbic.org/dod-worldwide-numbers-tbi>.
- Identification, surveillance, and burden of cases of military service-related TBI in veterans seeking care outside the VA system, which might include those who have not sought medical care or were not diagnosed while SMs in the military or VA health-care systems.

- Initiate research that examines disability, quality of life, and long-term outcomes associated with all severity levels of TBI.
- Add questions to federal or state sponsored population-based follow-up studies to determine the occurrence and the epidemiologic and clinical characteristics of the long-term consequences of TBI among eligible persons.
- Use existing civilian and military-related TBI surveillance systems and registries to develop prospective follow-up studies to determine the long-term epidemiologic, clinical, cognitive, and socioeconomic characteristics among eligible persons; and to determine if these persons have access to and receive appropriate social and rehabilitation services.
- Share TBI systems and registries available in the civilian, DoD, and VA Health Systems to determine the occurrence and the long-term medical and socioeconomic characteristics of TBI among eligible persons.
- Assess the burden of military service-related TBI in veterans receiving care outside the VA system. Routinely use the recommended federal TBI definitions when analyzing data from large national surveys and surveillance systems conducted by CDC/NCHS and other federal agencies (see Data Sources in Chapter VI).

Recommendations to Improve TBI Prevention

Ultimately the goal is to prevent the occurrence of TBI for SMs on- and off-duty. During off-duty hours and those retired from active duty, the risks are similar to the civilian population, with falls and motor- vehicle crashes among the major causes. Active-duty SMs face additional risk from blast and penetrating injuries. Further research is needed to ensure these risks are reduced. Where evidence-based strategies exist, it is imperative that there is strict adherence to those practices. The recommendations below focus on continued research to reduce risk factors, improve the quality of protective equipment, and ensure that current guidelines and evidence-based strategies are adhered.

- Enhance research to reduce the risk of TBI from blast injury.
- Research to promote adherence to current guidelines on returning to active-duty following TBI.
- Conduct more research to improve the quality of protective equipment such as helmets.
- Strengthen evidence on the risk and protective factors associated with a TBI or the prevention of a TBI. Research may include but is not limited to reducing use of alcohol, ensuring adherence to use of seatbelts, motorcycle helmets and other protective equipment.
- Provide meaningful education to veterans who have sustained a TBI, their families and their clinicians about the elevated risk for subsequent TBI and actions that can be undertaken to mitigate this risk.

Chapter 268

THE SPATIAL ANALYSIS OF AIR POLLUTION PARAMETERS (PM₁₀, SO₂ AND NO₂): A CASE STUDY OF THE MARMARA REGION (2014-2017)

Ozer Akyurek*

Geomatics Engineering Department, Kocaeli University, Kocaeli, Turkey

ABSTRACT

Air pollution is the increase of foreign matters in the air above normal number and density. This affects the health living creatures in a negative way or may cause physical injuries, while air pollution-related effects and health problems can be also observed in healthy people, in especially elderly people and children, air pollution creates serious health problems on human health and causes more than 3 million people's death every year. This necessitates the examining and monitoring processes of air pollution and taking precautions against it, whenever needed. In this study, spatial pollution distribution maps of the Marmara Region that receives migration in high amount because of the intensive industrial activity in Turkey, are created by the identification of air pollutant parameters' (PM₁₀, SO₂ and NO₂) patterns which are obtained by air quality monitoring stations of Marmara Clean Air Central and Ministry of Environment and Urbanization between the years of 2014-17.

Keywords: air pollution, geostatistical analysis, spatial analysis, GIS

INTRODUCTION

Urbanization is defined as the increase in the urban population by the breakdown of the population between the cities and rural areas, and by the migration of people from rural areas

* Corresponding Author's Email: ozerakyurek@gmail.com.

to the cities. It is argued that within the period between the 1800s to these days, world population approximately doubled and this increase brought significant problems. While the living rate was 2,4% in the locations that have 20.000 and more population in the 1800s, this rate increased to 4,3% in the 1850s and to 9,2% in the first years of the 1990s. The highest increase took place in the 1950s as 20,9%. Along with the rapidly increasing population in a very short time period, pollution in cities showed a rapid increase (Demirarslan and Akıncı, 2018; Partigöç and Cubukcu, 2017).

Air pollution is the increase of foreign matters in the air above normal number and density. This pollution that affects the health of living creatures' in a negative way or cause physical injuries. . Air layer, by getting polluted with the waste that emerges as a result of human beings' various activities and shows up during production and consumption activities, affects the life of human beings on earth in a negative way (Akyurek et al., 2013). Global warming, industrial activities, consumption of fossil fuel that are used in motor vehicles, uncontrolled population growth and unplanned urbanization are listed as the primary factors that cause increase in pollution (Partigöç and Cubukcu, 2017).

Particulate matters (PMs) are the tiny granular solid or liquid particles that are spreading in the atmosphere and stay suspended in air. PMs may consist of several natural and artificial sources like burning of fuels, diesel engines, construction and industrial activities, secondary aerosols (reactions of ammoniac, Sulphur and nitrogen oxides in the air), herbal pollens and dusts that are raised from the ground. PMs cause serious health problems according to their sizes. As the sizes of PMs become smaller, they enter into the deepest points of lungs and destroy the structure and chemistry of lungs.

Sulphur dioxide (SO₂) is a colorless, suffocating and acidic gas released by the burning of the Sulphur compounds that are found in its structure. Main existing Sulphur dioxide producing activities are industrial applications, domestic fuels that are used for heating purposes, steam power plants and the use of diesel vehicles (Akyurek et al., 2013; Demirarslan and Akıncı, 2018).

Nitrogen dioxide (NO₂) is a reddish-brown, pungent gas. Primary sources of NO₂ are the fuels that are used in vehicles, industrial plants and domestic heating. Its stay in the atmosphere changes according to the height. It can stay several months at the sublayers of the atmosphere, at the upper layers, on the other hand, it can stay only a few days. It causes serious problems in respiratory tracts and it may be fatal if it is inhaled in high doses (Cetin, 2006).

It is stated in the previous studies that long exposure to the air pollution has detrimental effects on human health. Diseases like cough, bronchitis, heart disease and lung cancer show an increase depending on the air pollution. While air pollution-related effects and health problems are also seen in healthy people, especially elders and children, it creates serious health problems on human health. Therefore, examining, monitoring and taking precautions for air pollution is a significant issue. This problem causes more than 3 million people's death every year.

Geostatistics is an applied branch of statistics and it is a set of statistical methods which are evaluated with spatial data in earth sciences. Apart from the classical statistical methods, population parameters can be estimated related to the examples that are depended on one another instead of the examples that are independent of each other rule. Geostatistical analyses are used for predicting the value of the locations, in which observation is not carried out. In this sense, continuous surface format maps of data are obtained by making

interpolation at the points that are not measured in the land (Akyurek et al., 2013). In literature, there are many studies that have investigated and analyzed air pollution via geostatistical methods (Elbir, 2004; Fedra and Haurie, 1999; Lin and Lin, 2002; David et al., 1997; Briggs et al., 2003; Chen et al., 2015; Hee-Jae and Myung-Jin, 2014; Xiao et al., 2014; Rohde and Muller, 2015; Matejicek, 2005; Song, 2008, Demirarslan and Akıncı, 2018; Kim et al., 2018, Moral et al., 2010, Esperanza et al., 2004, among others).

This study aims to create spatial pollution distribution maps of the Marmara Region, which receives migration in high amounts because of the intensive industrial activity in Turkey, by the identification of air pollutant parameters' (PM₁₀, SO₂ and NO₂) patterns which are obtained by air quality monitoring stations of Marmara Clean Air Central and Ministry of Environment and Urbanization between the years of 2014-17.

MATERIALS AND METHODS

Study area, the Marmara Region, is a region that is located between the 26° and 31° east longitudes, 38° and 42° north, hosts Turkey's cities which are developed industrially, and has 24,816,023 population according to the Turkish Statistical Institute's data and address-based population information. Increasing population and rapid industrialization bring along rural-urban migration movement. The Marmara Region, which is one of the important industrial zones of Turkey, and has been exposed to continuous movement of migration. It received 3,240,686 immigrants from the other cities between the years of 2014 and 2017, which is the period of study, according to the Turkish Statistical Institute's data. When the highest migration receiving cities are examined, cities like Istanbul, Bursa, Kocaeli and Tekirdag that have developed industrial activities, come to the forefront (Figure 1).

The increase in the urban population brings along various environmental pollution issues. One of the most important pollutions is the air pollution. Air quality monitoring stations have been established throughout the country since 2005 in order to detect, analyze and take necessary precautions, in a timely fashion, for air pollution. Air quality is monitored with hourly measurements by 125 stations that are established by the Ministry of Environment and Urbanization in 81 provinces and 39 stations that are established by the Marmara Clean Air Center. In many countries, limit values, which are determined by the European Union and World Health Organization, are used as the local limit values in order to keep air pollution under control. Limit values for air pollutants in long term, short term and winter periods are determined in the regulations of Air Quality Evaluation and Management that was published in 2008 in Turkey. PM₁₀ and SO₂ pollutants' limit values that belong to Turkish Limit Values, European Union and World Health Organization are shown in Table 1.

Table 1. PM₁₀ and SO₂ pollutants with the national and international annual limits

Pollutant	Turkish Limit Values (AQEMR) (µg/m ³)	EU Regulations (µg/m ³)	WHO Guidelines (µg/m ³)
PM ₁₀	44	40	20
SO ₂	20	20	-
NO ₂	44	40	40

Data used in this study is obtained by the 45 Air Quality Monitoring Stations that are located in the Marmara Region between the years of 2014 and 2017. Air Quality Monitoring Stations' locations are shown in Figure 2. Hourly recorded PM₁₀, SO₂ and NO₂ pollutant parameters are used in the analyses conducted by the transformation of daily values first, and then monthly and yearly values.

Figure 1. Migration distribution diagram according to the provinces.

The problem of classical statistical methods is the assumption that data variables are independent of each other. It is not possible to obtain exact statistical independence for the values that are distributed in a specific structure. According to Tobler (1970), closer things are more related to each other than the further ones. The spatial dependence, which is defined as the observations that are close to each other are more similar than the observations that are remote to each other, invalidates classical statistics' independence assumption (Atkinson, 2002). Geostatistics is a statistical calculation method that approaches the relationship among the data by also taking account of their locations. The method has significant advantages like the detection of the error quantity at particular confidence levels. Geostatistical analyses are used for predicting the values of the locations, in which observation is not carried out. In this sense, continuous surface format maps of data are obtained by making interpolation at the points that are not measured in the land. These operations consist of two parts: modelling (semivariogram calculations) and spatial interpolation (Kriging method). The semivariogram is the calculation of the sample variance's change with the distance. Closer samples show similar variance value and generally show an increase with the distance between variance samples compared to the distant ones. The Kriging method, on the other hand, is used to predict features of spatial structure between the samples that are obtained by the semivariogram calculations, at the points that sampling is not done (Akyurek et al., 2013; Yesilkanat et al., 2014).

Figure 2. 45 Air quality monitoring stations available in the Marmara Region.

The semivariograms are specified for the study area, in which the measurement is made, as in the equation below;

$$\gamma(h) = \frac{1}{2N(h)} \sum_{i=1}^{N(h)} \left(Z(x_i) - Z(x_j + h) \right)^2 \quad (1)$$

Here, $\gamma(h)$ demonstrates the semivariance value, the distance between h , i and j points, $N(h)$ demonstrates the number of dot pairs at h distance, $Z(x_i)$ demonstrates the measurement value of data in the data set at the i point and $Z(x_j+h)$ demonstrates the measured value of the data in h distance.

One of the semivariogram parameters as seen in Figure 3, nugget, is the point where the theoretical curve intercepts vertical axis at $h=0$ point. It does not affect the prediction value, it only causes change in the Kriging variance. Partial Sill is the vertical scale value for the structural components of the variogram. Range is the horizontal distance of the variogram. After this length, the data are uncorrelated with each other. The variogram or covariance values remain stable after this length. The change in the range causes also the change of interpolation value. The Llag distance is the horizontal distance between the sampling points and inter sampling points or interpolation points. The sill is the total vertical scale value of the variogram function. It does not affect the prediction value, it only causes change in the Kriging variance (Akyurek et al., 2013).

The Kriging, which is the geostatistical analysis method at Geostatistics, is used to determine the quadrennial air quality in the area examined, and it is carried out by aiming to map spatial distribution of the pollutant parameters by the geostatistical analysis.

Figure 3. The semivariogram model and its parameters.

RESULTS AND DISCUSSION

The annual mean values that are calculated from the pollutant parameters (PM_{10} , SO_2 and NO_2) and obtained as hourly average from the 45 Air Quality Monitoring Centers in the Marmara Region between the years of 2014 and 2017, are used in the study. Firstly, the comparison of the limit values is carried out with the calculated annual means. Accordingly, the number of the stations that exceed the limit values according to the Turkish Limit Values are detected and shown in the Table 2.

When the number of the stations, which exceed the limit values are examined, for the particular matters and SO_2 , it is found that they are the air quality stations in which industrial plants are located generally. It is observed that the limit values exceeded especially in the stations that were in Istanbul, Bursa, Tekirdag and Kocaeli. Also, the PM_{10} and SO_2 values were calculated far above the limit values in Kesan province that used solid fuel for domestic heating and the Can province that had thermal power plant within its borders, during the time period when the data were collected. It is observed that the SO_2 values that were calculated in Kesan and Can were ten times higher than the limit values. When the stations that exceeded the NO_2 limit value were examined, it was evident that these stations were the stations in the provinces that generally had high values in terms of population. The main sources of the NO_2 were the fuels that were used by the vehicles which re used for transportation and industrial plants. When the quadrennial period was examined, the NO_2 value was calculated above the limit values especially in the stations in the provinces that weres crowded both in terms of population and industrial plants such as Istanbul and Bursa.

In the creation of the spatial distribution maps, the weights and possibilities that were determined by the semivariograms by the help of ordinary Kriging method, were used. With the help of this method, the pollution distribution maps of three pollutant parameters were created belonging to four different years (from 2014 to 2017).

Table 2. The number of stations that exceed the Turkish Limit Values by years

	PM ₁₀	SO ₂	NO ₂
2014	18	6	8
2015	20	8	7
2016	18	13	8
2017	21	10	8

The distribution maps that belonged to the PM₁₀ pollutant parameter are shown in Figure 4. In Figure 4-a, in the distribution map that belonged to 2014, it is seen that Bursa province, which is one of the industrial cities of the Marmara Region, and Istanbul Esenyurt district were high in terms of the PMs . Also, it was observed that PM densities in the air were above the limit values in Kesan, Can and Bozuyuk districts and also in Tekirdag city center. In Figure 4-b, it the distribution map that belonged to 2015, it is seen that PM density in Esenyurt and Tekirdag city center was higher than the previous year. In other centers, on the other hand, it is observed that it remained at similar levels. In Figure 4-c, in the distribution map belonging to 2016, it is seen that pollution level went down the limit level and below in the other stations except in Tekirdag city center and the Bursa province. In Figure 4-d, in the distribution map that belonged to 2017, it is seen that pollution level maintained the tendency of the previous year.

The biggest source of the SO₂ pollutant is the solid fuels that are used for domestic heating. Because of the fuels that have high Sulphur rate are not burned properly, the Sulphur amount extracted to the atmosphere is measured very high in the locations that use solid fuels for domestic heating. The SO₂ pollutant parameter's distribution maps are shown in Figure 5. In Figure 5-a, the distribution map that belonged to 2014 is shown. It is seen that the values were exceedingly above the limit value in Edirne's Kesan district that used stove and its derivatives for domestic heating during the time of data collection and Canakkale's Can district that had coal-fired thermal power plant, which was used for power generation within its borders. Also, it is found out that calculated values were above the limit values again in the Bursa province and Kocaeli's Kandira district. The distribution maps that belonged to 2015 and 2016 are shown in Figure 5-b and c. It is seen that the values in Kesan and Can districts were still far above the limit values although the other stations went down the limit value level. In Figure 5-d, it is observed that the SO₂ level measured in the stations, fell down thanks to the precautions taken. It is seen that while the measured pollutant values reached the limit values in Can, they were at lower levels compared to the previous years in Kesan.

The biggest sources of the NO₂ pollutant are the fuels that are used at the transportation vehicles, industrial plants and fluid fuels that are used for the domestic heating. The distribution maps that belong to the NO₂ pollutant parameter are shown in Figure 6. In Figure 6-a, in the distribution map that belonged to 2014, it is seen that the NO₂ pollutant parameter was close to the limit value and above in Istanbul, Bursa, Kocaeli and Tekirdag provinces that had industrial plants intensively, were the highly populated provinces and had the highest migration rates every year. In Figure 6-b and c, a similar situation is seen in the distribution maps that belonged to 2015 and 2016. But in Figure 6-d, in the distribution map that belonged to 2017, it is seen that the measured values distributed to the entire provincial border with a rapid increase especially for Istanbul and Bursa.

Figure 5. The SO₂ Pollutant's Distribution Maps; a) 2014, b) 2015, c) 2016 and d) 2017.

Figure 6. The NO_2 Pollutant's Distribution Maps; a) 2014, b) 2015, c) 2016 and d) 2017.

CONCLUSION

In this study, the pollutant parameters' distribution maps by years were created by using spatial analysis of the air pollutant parameters that were measured by 45 Air Quality Monitoring Stations in the Marmara Region between the years of 2014 and 2017. With Geostatistics technique, the spatial pollution distribution maps were created by the identification of spatial patterns regarding to the air quality parameters and the station-based statistics were evaluated with the dynamic mapping. The findings of this study revealed that the Geostatistics-based spatial statistical applications are an effective tool for the air quality management.

It was observed in the maps, which were used in this study that PMs showed higher distributions in the locations that had more amount of industrial plants and they reached to high values also in the locations that used solid fuels for domestic heating. When the SO_2 's distribution maps were examined, the Kesan and Can districts reached to excessive values in terms of this pollutant but it was observed in the distribution maps that precautions taken were effective. When the NO_2 's distribution maps were examined, it was observed that the cities that had higher population density, had higher values in terms of this pollutant. The effect of population on this parameter might be clarified with intensive vehicle traffic, fluid fuels that were used for heating and intensive industrial plants.

Air is a vital environmental element. This environmental element, which is vital to maintain life, is essential for human life as a physical factor. The air is breathed between ten

thousand and twenty thousand liters per person in a day. The air that is used in such a high rate must have high quality. Low air quality causes fatal effects. Air quality needs to be examined regularly and kept under control. Geostatistics is an effective tool for monitoring and examining air quality. The pollution distribution maps that are created with the help of Geostatistics, turns into a source of information that provides prominent information for air quality determination and enhancement. It provides useful information to the decision-makers for the precautions that will be taken in the future. With the help of spatial mapping that can be updated instantly, people will be provided with information about the quality of the air they breathe and decision makers can provide a healthier environment and clean air for the people who live in these places.

Chapter 269

OBESITY, OBESITY SURGERY AND NURSING CARE

Züleyha Şimşek Yaban

Nursing, Kocaeli University, Faculty of Health Sciences, Kocaeli, Turkey

ABSTRACT

Obesity is not just an emerging health problem, it also leads to other public health problems, including: diabetes, hypertension, cardiovascular diseases, cancer, depression, infertility, and it negatively affects social life as well. In the simplest terms, obesity is an energy irregularity characterized by abnormal or excessive fat accumulation.

The increase in obesity incidence is a common situation for all countries that is parallel with their development level and increased consumption of ready-to-eat foods. According to the World Health Organization (WHO), obesity has increased nearly threefold worldwide since 1975. In 2016, more than 1.9 billion adults over 18 years of age were overweight, and over 650 million of them were obese. The obesity rate in Turkey was 15.2% in 2008, and it increased by 31.1% and reached 19.9% in 2014. Globally, many factors contribute to increasing in obesity rates due to reduced physical activity as a result of jobs that require minimal physical activity become more common, less mobility, changing modes of transport, the consumption of fatty and high calorie foods and increased urbanization.

Obesity is an important public health problem in our country and worldwide, and it causes a variety of physiological, psychological and social complications by negatively affecting obese people's quality of life and many organ systems in their bodies. Although diet, physical activity, psychological support and pharmacotherapy are commonly used treatments for obesity, obesity surgery (bariatric surgery) has recently emerged as a contemporary treatment modality.

The success of obesity surgery requires a multidisciplinary team approach including surgeons, psychiatrists, nutritionists, nurses, physiotherapists and other health professionals from the moment patients apply to hospital until being discharged. It is also very important to meet special needs due to the accompanying diseases of obesity surgery patients.

Providing personalized, individualized and holistic nursing care and counseling services to the patients who will undergo obesity surgery patients to reduce possible risks in their care, and preventing complications and difficulties before, during and after

surgery are very crucial. These services are also important to increase patients' quality of life.

Keywords: obesity, obesity surgery, bariatric surgery, nursing care

INTRODUCTION

Nowadays, obesity is considered as a chronic, progressive and life threatening disease because of the comorbidities and obesity-related psychological problems. Obesity which is defined as “excessive fat accumulation in the body to the extent that derange health” by the World Health Organization (WHO), is a disorder that needs to be treated endocrinally, metabolically, and psychologically. Normally, fat tissue constitutes 15-20% of body weight on average in adult males while it constitutes 25-30% of body weight on average in adult females. When the ratio of fat tissue exceed 25% of body weight in males and 30% of body weight in females, this condition is called as obesity (Bozbora, 2002; Turkish Public Health Institution, 2013).

The prevalence of obesity which has become an increasingly important health problem, increases in all ages and socio-economic groups in all developed and developing countries. According to the obesity rates in the Organisation for Economic Cooperation and Development (OECD) countries, the ratio of obese persons in the adult population is 19.5%. This rate varies according to countries, it is lower than 6% in Korea and Japan and higher than 30% in Hungary, United States of America, New Zealand and Mexico. More than a quarter of adult population is affected by obesity in the United Kingdom, Chile, Australia, Canada and South Africa. The ratio of overweight and obese individuals has increased in the United States, France, Mexico, Canada and Switzerland while it has not changed in Korea, Spain, England and Italy within last decade (OECD, 2017). In Turkey, the obesity rate was 15.2% in 2008, increased by 31.1% and reached to 19.9% in 2014 (TUIK, 2015). According to the OECD 2017 data, the prevalence of obesity in Turkey (22.3%) is higher compared the average obesity prevalence in the OECD countries. Obesity rates are expected to be high especially in the United States (47%), Mexico (39%) and England (35%) in the year of 2030 (OECD, 2017).

Obesity is accepted as a natural consequence of modern life by many individuals while it is usually related with diseases such as cardiovascular diseases, metabolic syndrome, type 2 diabetes mellitus (DM), a decrease in physical activity due to lifestyle especially in transportation, production and agriculture along with advancing technology, the changing eating habits in modern life play roles in the increasing prevalence of obesity. Fast-food is a diet being rich in terms of fast-eating unhealthy foods, carbohydrates and refined sugar and which is poor in terms of vegetable fiber, leads to obesity. In addition, the widespread use of high-tech devices (mobile phones, televisions, computers, home cinema systems, etc.) that easily fill our leisure time, has an important contribution to the increase of obesity. In addition, endocrine disorders such as diabetes mellitus, hypothyroidism, growth hormone deficiency and drugs that disrupt metabolic control such as antipsychotics, glucocorticoids, anabolic steroids also play an important role in increasing prevalence of obesity (Turkey Endocrinology and Metabolism Society, 2017; Turkish Public Health Institution, 2013).

Nowadays, there are three methods to determine obesity. These three methods are ideal weight, body mass index (BMI or Quetelet index) and the measurement of subcutaneous fat. Individuals having a body weight which is 10% higher than ideal weight, are defined as overweight while individuals having a body weight which is 20% higher than ideal weight, are defined as obese. BMI is a practical method used to classify obese people and to plan treatment methods (Asoglu, 2008; Bozbora, 2002). The World Health Organization (WHO) defines overweight and obesity based on body mass index ($\text{BMI} = \text{Weight [kg]} / \text{Height [m}^2\text{]}$). According to this definition, individuals having a BMI between 18.5-24.99 kg/m^2 are classified as normal weight; individuals having a BMI between 25.0-29.9 kg/m^2 are classified as overweight; individuals having $\text{BMI} \geq 30 \text{ kg/m}^2$ are classified as obese; individuals having a BMI between 30-34.9 kg/m^2 are classified as class 1 obese; individuals having a BMI between 35-39.9 kg/m^2 are classified as class 2 obese; individuals having a $\text{BMI} \geq 40 \text{ kg/m}^2$ are classified as class 3 obese (Turkey Endocrinology and Metabolism Society, 2017; WHO 2018). In the measurement of subcutaneous fat tissue, which is another method for the diagnosis of obesity, the sum of the thickness of skin across scapula and triceps which is $>55 \text{ mm}$ in females and $>32 \text{ mm}$ in males is defined as obesity (Bozbora, 2002).

Obesity creates a fertile environment for the development of many health problems such as cardiovascular diseases, hypertension, diabetes, certain types of cancer, respiratory system diseases, musculoskeletal system diseases. It also increases health care expenditures and negatively affects the quality and duration of life (Turkey Endocrinology and Metabolism Society, 2017). Advanced obesity is often called as morbid obesity because of the diseases associated with obesity. Morbid obesity is a metabolic disease and is associated with numerous medical problems. In fact, most of these problems are not observed in the absence of obesity while many health problems arise with weight gain. The most common problems are arthritis and degenerative joint diseases; at least 50% of the patients who undergo surgery due to morbid obesity have these accompanying diseases. Premature deaths are more frequent in children of obese individuals; the death rate of morbid obese individuals is 12 times higher compared to normal-weight individuals in 25-35 years old male individuals. Obesity is observed in 25% of asthmatic patients, 30% of hypertensive patients, 20% of diabetic patients and 20-30% of the patients with gastroesophageal reflux. The incidence of these comorbid diseases increases according to the duration of obesity and age. The number of comorbidities (Bozbora, 2002; Sakrak and Dikmen, 2010), socioeconomic problems, psychological disorders and premature death risk increase in patients over 50 years of age (Asoglu, 2008).

TREATMENT OF OBESITY

The goal of obesity treatment is to alleviate obesity-related morbidity and mortality risks, to bring individuals adequate and balanced nutrition habits and to improve the quality of life (Turkey Endocrinology and Metabolism Society, 2017). Obesity is a global pandemic and is also considered as a treatable and preventable health problem. It can be treated by medical nutrition (diet), physical exercise, behavioral change, pharmacological and surgical methods (Alican, 2007). The diet succeeds only in a small part of the patients and does not take a long time for the patients to regain their lost weight. An effective and safe pharmacological agent has not been developed in the treatment of obesity. Pharmacological preparations in use are

not effective or not preferred due to their adverse effects. In this context, it has been stated that diet, physical exercise and behavioral change are indispensable in obese patients while pharmacological and surgical treatment can be applied if required. Surgical treatment may be effective for the treatment of morbid obese patients (Asoglu, 2008; Yuksel, 2016).

Medical Treatment

Obesity treatment is a combination therapy that includes lifelong adequate and balanced nutrition, increased physical activity and behavioral therapies. Essentially, medication is not recommended for the treatment of obesity at the beginning. However, drug treatment may be applied temporarily for selected patients (patients in the high-risk group ($BMI \geq 30 \text{ kg/m}^2$)) by an endocrinologist (Turkish Public Health Institution, 2013).

In obesity treatment, behavioral change therapy is absolutely necessary along with nutritional therapy and increased physical activity. In combined treatment, nutritional therapy, exercise and behavioral change therapy are used in combination and provide great success in both weight loss and maintenance of weight loss. The goals of medical nutrition therapy in obesity are:

1. To provide adequate and balanced nutrition which is appropriate for the individual's age, gender, physical activity status, life style and physiological condition.
2. To provide proper and lasting nutrition habits instead of wrong nutrition habits.
3. To decrease the body weight to the desired level (this level may be an ideal weight or a weight over ideal weight).
4. To stop regaining weight, thus individuals lost body weight and to keep it at the desired level lastingly.
5. To maintain normal growth and development in children (Turkey Endocrinology and Metabolism Society, 2017).

Surgical Treatment

The surgical treatment of obesity is the only proven method for achieving long-lasting weight loss by controlling and potentially resolving life-threatening comorbidities and improving the quality of life of morbid obese patients at the same time. It was showed that the expected length of life increased by 12 years after the surgical treatment of obesity (Frantzides et al., 2013). Obesity surgery (bariatric surgery) is one of the increasingly popular obesity treatment methods in the world in the last decade. The number of patients undergoing bariatric surgery increase day by day because obese patients lose weight rapidly in addition to a decrease in comorbid diseases after bariatric surgery (Yuksel, 2016).

The aim of surgical treatment is to reduce morbidity and mortality due to obesity and to improve metabolism and organ functions. Thus, obesity-related comorbidity, drug expenditure and time lost due to being ill decrease while the quality of life improves (Turkey Endocrinology and Metabolism Society, 2017).

Despite the significant developments in technique, care and follow-up in bariatric surgery, the risk and perioperative complications have not been alleviated. Therefore the selection of appropriate patient and appropriate technique is very important (Turkey Endocrinology and Metabolism Society, 2017). A bariatric surgical team consists of an endocrinologist, nutritionist, anesthetist, operating room nurse, operating room technician, nurse care coordinator (advanced nurse or a well-educated nurse), a psychiatrist, a psychologist, cardiac, pulmonary, gastrointestinal, endocrine, musculoskeletal and neurological specialists (Frantzides et al., 2013; Sakrak and Dikmen, 2010; Turkish Public Health Institution, 2013; Yurdakul, 2015).

The selection of an appropriate patient should be meticulously performed according to the recently adopted criteria of the National Health Institution (NIH) independently of the type of surgery, to be able to perform bariatric surgery. For performing bariatric surgery, a patient must have a Body Mass Index (BMI) ≥ 40 kg/m²; if a patient's BMI is >35 kg/m², he/she must have obesity-related comorbidities (Type 2 diabetes, severe HT, arthritis, sleep apnea syndrome, etc.), inability to control it with medical treatment and lifestyle changes, previous unsuccessful attempts with non-surgical methods (diet, medicine, etc.), an age between 18 and 60 years and the duration of obesity >5 years (Bozbora, 2002; Frantzides et al., 2013; Sakrak and Dikmen, 2010; Turkey Endocrinology and Metabolism Society, 2017). The inability to adapt daily life conditions because of obesity and having some psychological problems due to obesity are relative indications for surgical intervention. Inability to follow the postoperative follow-up protocol, excessive amounts of medication, alcohol or drug use, mental retardation, the presence of brain tumors affecting the satiety center and severe psychiatric disease (major depression and psychosis) or advanced cardiac disease are among the contraindications for surgical intervention (Bozbora, 2002; Turkey Endocrinology and Metabolism Society, 2017).

The surgical treatment of obesity (bariatric surgery) is preferred more compared to the past in which applied surgical procedures lead to weight loss by causing malabsorption or restricting food intake. There are also combined surgical procedures that use both methods together (Turkey Endocrinology and Metabolism Society, 2017).

- a) Restriction of Food Intake: The food storage capacity of the stomach is reduced by resection, bypass or narrowing the upper part of the stomach of the patient, thus the patient consumes less food. Vertical band gastroplasty (VBG), sleeve gastrectomy (SG) and laparoscopic adjustable gastric band (LAGB) are restrictive surgical procedures. There is no change in the absorption function of small intestine after these procedures (Turkey Endocrinology and Metabolism Society, 2017).
- b) Surgery for malabsorption: Nutrient absorption is reduced by shortening the length of the small intestine by bypassing the absorbing area or by distracting the bileopancreatic secretions facilitating absorption. Jejunoileal bypass (JIB) and duodenal switch (DS) are these type operations. However, protein-calorie malnutrition and the deficiency of some micronutrients develop when the malabsorption is too high (Turkey Endocrinology and Metabolism Society, 2017).
- c) Restrictive and malabsorptive, combined effective procedures: Roux-en-Y gastric bypass (RYGB), biliopancreatic diversion (BPD) and biliopancreatic diversion / duodenal switch (BPD / DS) are these type operations. In RYGB, malabsorption is

provided with small intestine reconstruction while restriction is provided with small stomach pouch (Turkey Endocrinology and Metabolism Society, 2017).

Totally, 468,609 bariatric procedures was performed in 2013 while 95.7% of the procedures were carried out laparoscopically according to the International Federation for the Surgery of Obesity and Metabolic Disorders (IFSO) consisting of 50 nations or national groups. The highest number (n = 154, 276) of procedures was performed in the USA/Canada region. Roux-en-Y gastric bypass (RYGB) was the most common procedure in the world with the ratio of 45%; sleeve gastrectomy (SG) was the second most common procedure with the ratio of 37%; adjustable gastric banding (AGB) was the third one with the ratio of 10%. The prevalence of SG increased from 0% to 37% worldwide from 2003 to 2013 while the prevalence of AGB decreased from its' peak to 68% from 2008 to 2013. SG is currently the most frequently performed procedure in the USA/Canada and in Asia/Pacific regions and second most frequently performed procedure after RYGB in the Europe and Latin America/South America regions (Angrisani et al., 2015).

NURSING CARE IN OBESITY SURGERY

The presence of comorbidities such as diabetes, hypertension and respiratory problems caused by obesity requires that the care of the patients undergoing obesity surgery before, during and after the surgery should differ from the care of other patient groups.

Preoperative Nursing Care

- It is very important that the patient is prepared well before the surgery for success in the obesity surgery. The patient's anxiety must be reduced by giving information about the needs of the patient before, during and after the surgery (Bozbora, 2002).
- Other risk factors leading to obesity such as gender, age, educational level, occupation, marital status, monthly income level, number of pregnancies and deliveries, smoking, alcohol use, psychosocial factors and chronic stress, drugs (antidepressants, antiepileptics, corticosteroids, progestational steroids, hormonal contraceptives, etc.) and the symptoms of the diseases leading to secondary obesity, obesity complications, the symptoms of the comorbidities (type 2 diabetes, HT, dyslipidemia, cardiovascular and respiratory diseases, joint diseases, non-alcoholic fatty liver disease (NAFLD) and sleep disorders) must be examined (Turkey Endocrinology and Metabolism Society, 2017).
- During the preparation period, blood tests (hemoglobin, hematocrit and whole blood count, prothrombin (PT) and partial thromboplastin time (PTT), cholesterol, triglyceride, urea, creatinine, electrolyte levels), urinalysis, radiological examinations (chest X-ray, gallbladder and liver ultrasonography), cardiogram and echography and tests for special conditions due to obesity must be performed (Bozbora, 2002; Garza, 2003; Sakrak and Dikmen, 2010).

- Determining the level of nutrition during the routine examination of the patient is very important in terms of the effectiveness of the treatment methods to be performed. This assessment includes the size and weight of the patient, nutritional anamnesis, anthropometric measurements and physical examination (Bozbora, 2002; Neil, 2013; TUIK, 2015). The food preferences of the patient, the amount and time of eating must be found out. The status of having a chronic, systemic disease is important in evaluating the nutritional status of the patient (Bozbora, 2002).
- In morbid obese, important physiopathologic changes are observed in the gastrointestinal cardiovascular and respiratory systems. In obese patients, oxygen consumption and carbon dioxide production increase in the respiratory system because of the high energy consumption and metabolic demand (Tanaka and Peniche 2009). When sleep apnea is diagnosed, a treatment such as continuous positive airway pressure (CPAP) can be started before surgery and some arrangements are made to monitor O₂ saturation of patients via pulse oximetry; CPAP can be continued after surgery (Garza, 2003).
- In the preparation of the patient for laparoscopic bariatric surgery, mechanical bowel cleaning is performed for 2 days. Patients are free to drink water until one day before surgery therefore they are protected from dehydration (Sakrak and Dikmen, 2010).
- The patient must take a shower to clean the skin before the obesity surgery. Skin hairs must also be removed with epilators or hair removal creams if necessary.
- Skin risk assessment (e.g., Braden Score) must be performed at hospital admission, with continuous monitoring during hospitalization and follow-up care of infection, ulceration of skin folds, irritation, atypical and pressure ulcers (Mulligan et al., 2009).
- Chairs, operating room tables, stretchers, wheelchairs, commodes, patient scrubs and sphygmomanometer cuffs must be prepared in sizes which are suitable for the patient before surgery. In order to ensure the confidentiality of the patient, the patient must be allowed to live alone in a private room (Asoglu, 2008).
- Before the surgery, wide vein path are opened with a foley catheter for each patient. In super obese patients, foley catheter placement maybe difficult due to covering of the perineum by the belly. In obese patients with increased subcutaneous fat tissue, central venous catheterization should be preferred because of the difficulty of finding a peripheral vascular access and the difficulty of maintaining continuity in the postoperative period. Arterial catheterization for invasive blood pressure monitoring facilitates blood pressure monitoring in the early postoperative period in intensive care (Asoglu, 2008; Otmalaz and Ece, 2016).
- The importance of early post-operative ambulence, deep breathing and coughing exercises and the use of spirometers must be emphasized and taught to the patient (Garza, 2003).
- Prophylaxis is provided against deep vein thrombosis (DVT) and pulmonary embolism. For this purpose, important measures are taken such as early mobilization within 4-6 hours after surgery, the use of pressure socks and shoes to pressure lower extremities and subcutaneous administration of low molecular weight heparin. High-risk patients need to administer heparin for 2 weeks after discharge therefore

subcutaneous administration must be taught to high risk patients before discharge (Sakrak and Dikmen, 2010).

- Patients' post-operative anticipations must be discussed with them, to ensure that their goals are realistic. They must be informed about all possible complications in detail and their written consents should be obtained (Turkey Endocrinology and Metabolism Society, 2017).
- The preoperative nurse needs to note abnormalities about the patient, adds them in the care plan and shares their concerns with the surgeons and anaesthesiologists.

Intraoperative Nursing Care

- While the standard operating tables have a weight limit of 200 kilograms, the weight limit of the tables designed for bariatric surgery is 450 kilograms. Since most of the bariatric interventions may be required to position the patient, it must be ensured that the patient does not fall from the table and is safe (Asoglu, 2008). The nurse must ensure that adequate number of personnel are in the operating room to safely move and position the patient (Neil, 2013).
- The healthcare staff must be attentive to protect the patient from pressure ulcers and nerve damages by supporting pressure points with pads. This is especially important for advanced obese and diabetic patients (Asoglu, 2008). In the intraoperative period, the nurse, who is primarily responsible for the safety and care of the patient, should take necessary precautions and applied interventions to prevent pressure sores during the operation.
- The perianesthesia nurse needs to be prepared to help the positioning of the patient for ideal tracheal intubation (Mulligan et al., 2009).

Postoperative Nursing Care

- Vital findings that provide a potential sign to important problems should be evaluated carefully. Patients should be monitored for the first 24 hours after surgery for the complications such as hypoxia, hypercapnia and sleep apnea (Turkey Endocrinology and Metabolism Society, 2017).
- Oxygen saturation should be monitored by pulse oximeter for the first 24-48 h after surgery. So emergency tracheostomy may be required, the necessary equipment have to be available at the bedside.
- The pain management is very important for the patients' early ambulation, spirometer use and participation to deep breathing and coughing exercises. A PCA (patient controlled analgesia) device must be provided to the patient, thus the patient keep his/her pain under control. Pain control is important for ambulation and breathing exercises, both of them are important to protect the patient from respiratory problems such as atelectasis or infection and thrombosis (Mulligan et al., 2009; Owers et al., 2012; Sakrak and Dikmen, 2010).

- Morbid obese patients have decreased blood supply due to excessive fat tissue while wound healing is also delayed in these patients. Therefore nurses must perform daily wound care and dressing to prevent delay in wound healing due to infection, and observe wounds in terms of color and drainage (Barth and Jenson, 2006).
- The prevalence of venous thromboembolism is higher in obese patients, because of that ambulation and physical activity are important. Nurses must observe the patient for venous thromboembolism symptoms (e.g., swelling, pain or tenderness, warmth, or redness in legs or one leg) and note information about their observations in the postoperative teaching materials. Compression socks, early and frequent ambulation, leg exercises in the bed once in two hours, anticoagulant or low-molecular-weight heparin must be applied as a common prophylactic intervention to prevent DVT (Barth and Jenson, 2006; Mulligan et al., 2009; Neil, 2013; Sakrak and Dikmen, 2010; Tanaka and Peniche 2009).).
- It is very important to monitor fluid intake and fluid loss of the patient and proper liquid replacement system functions (Barth and Jenson, 2006; Mulligan et al., 2009). Fluid electrolyte imbalances due to overfeeding and heavy diets should not be overlooked.
- In the postoperative period, cardiac rhythm and blood pressure must be monitored at regular intervals to be aware of the increase in heart rhythm, one of the symptoms of complications such as hemorrhage and anastomosis (Barth and Jenson, 2006; Neil, 2013).
- Diabetic subjects must be monitored in terms of blood glucose level and hypoglycemia (Turkey Endocrinology and Metabolism Society, 2017).
- It is important to position the patient. The weight of the abdominal contents compress the diaphragm and makes breathing more difficult, therefore the standard supine and Trendelenburg positions must be avoided. For preventing respiratory distress, the patient's head and neck must be raised 30°-45° to be flat, and the improvement of tidal volume should be allowed (Barth and Jenson, 2006; Mulligan et al., 2009; Neil, 2013).
- In patients undergoing obesity surgery, sleep apnea incidence is high. Nurses must be aware of potential undiagnosed sleep apnea in patients undergoing obesity surgery (Neil, 2013).
- The most lethal complication of bariatric surgery is leakage from the gastrointestinal system. Tachycardia, occasional tachypnea and agitation can be the only signs of a serious intraabdominal problem (Sakrak and Dikmen, 2010).
- The ambulation of the patient must be started as early as possible, the nurse must ensure that required equipments are available to help the patient for upstanding and position changing. Use of special bariatric beds, air-assisted transfer devices, mechanical patient lifts, bed trapezes and other equipment helps ensuring the safety of nurses and patients in the mobilisation and positioning of patients (Barth and Jenson, 2006; Mulligan et al., 2009; Neil, 2013).
- In restrictive and disruptive surgery or combined techniques, oral feeding is not started at early period due to impaired gastrosintestinal integrity and the adaptation of patients to the newly created gastrointestinal system anatomy takes time. Nurses'

support for nutrition during the hospitalisation period reduces patients' anxiety (Otmalaz and Ece, 2016).

- The written materials which contains information about the progression of the diet, appropriate food choices, bowel habits changes, drugs, physical activity, wound care, signs and symptoms to report to the physician, follow-up visits, vitamin and protein supplements, and the importance of drinking required amount of liquid (hydration) after discharge, should be provided to patients (Garza, 2003).
- Long term psychological support should be provided to the patients from the preoperative period to postoperative period, so the problems such as low self esteem, decreased socialization, intensive shame and fear can be alleviated (Barth and Jenson, 2006).
- Nurses need to know probable difficult parts of the care of obese patients. For instance, they have higher difficulty in urinary catheter and intravenous access placement, have changed social, emotional or psychological necessities, need higher amount of time for dependent-care requisites. It is very important to perform nursing care and to determine nursing diagnoses and plan nursing care.

CONCLUSION

Obesity is a chronic and relapsing disease due to it's complications and comorbidities. It is a complex disease and a result of genetic, environmental, biological, sociocultural and behavioral factors. Obesity has an increasing prevalence in the world and decrease the quality of life. It is an important health problem in terms of community health due to the related cardiovascular, pulmonary, endocrine, metabolic, psychological and other diseases. Obesity can be treated with surgical intervention and a multidisciplinary team approach. It is very crucial to provide personalized, individualized and holistic nursing care and counseling services to patients who undergo obesity surgery for reducing possible risks in their care and preventing complications and difficulties before, during and after surgery. These services are also important to increase patients' quality of life.

Chapter 270

EFFECT OF GLOBAL CLIMATE CHANGE ON OCCUPATIONAL HEALTH: HEAT STRESS

Serap Aarsal Yildirim

KOÜ Kocaeli Vocational School of Health Services,
Emergency and First Aid Program, Turkey

ABSTRACT

The potential consequences of global climate change have been investigated over the past 20 years, and researchers believed the elderly, newborn, or pregnant people, especially those in the equatorial countries and small islanders are at risk. In addition to these risk groups, another risk group is the workers working outside with brute strength.

The American National Institute for Occupational Safety and Health (NIOSH) reported 423 deaths between 1992 and 2006, mainly due to the rise in temperature and heat waves. Causes of these deaths are often identified as “heatstroke” and other heat-related diseases. It has been determined that 24% of these people were working in forestry, agriculture, fishing, and hunting fields.

The publications between June-July 2018 were scanned through the “PubMed,” “CDC” and “WHO” official websites, and the literature on heat stress was examined related the effects of global climate change on occupational health.

This study emphasizes the effect of greenhouse gases emitted uncontrollably and intensely to the atmosphere with the Industrial Revolution on working health as a cause of global climate change.

Keywords: global climate change, occupational health, heat stress

INTRODUCTION

Without greenhouse gases such as carbon dioxide, the earth’s temperature would be around -18°C, and it probably wouldn’t be possible to talk about life as it is today. With

technological improvements, the release of greenhouse gases has also increased, and it has brought a new predicament over the years, global climate change.

Global climate change is making radical changes that cause degradation of ecological balance such as temperature increase, extreme weather phenomena, natural disasters, deterioration of water cycle, change in air quality, increase in sea level, and in human life such as ecological migration, new diseases.

Between the years of 1860-2000, it is recorded that the temperature increased in the world is between 0,5-0,7°C (Brass, 2002). Depending on the climate change caused by human or natural factors, a temperature increase of only 2-4°C is expected in this century alone (Brass, 2002; Alley et al., 2007; Kjellestrom et al., 2011).

Global climate change has direct effects such as an increase in temperature, changes in ozone activity, increase in solar radiation due to the variety of air pollutants, and rise in air moisture content are among the predictions (Grandi et al., 2016). These changes are accompanied by indirect effects such as deterioration of human health. In a report published by the International Panel on Climate Change (IPCC) (2014), among the health problems to be encountered in the future due to the consequences of global climate change, lethal hot strokes, heart attack, drought-related nutritional disorders and infectious diseases, injuries due to extreme air temperatures were found to be equally possible (Smith et al., 2014).

Considering about 1/3 of human life is spent on working, it is one of the expected results that climate change affects work life along with occupational health.

Increased exposure to solar radiation, increase in toxic effects of certain chemical substances due to temperature increase, increase in the number of vectors and pathogens, loss of former value due to the migration of workforce due to migrations, workplace violence or precarious work, work accidents due to extreme temperatures are among the future risks threatening the occupational health and safety. Particularly, the sectors most affected by climate change are the ones that complete the majority or most of their shifts in the outdoor environment or in isolation exposed to extreme temperatures, radiation and high humidity such as agricultural workers, road and construction workers, archaeologists, fishermen, firefighters, disaster emergency workers in fire brigade and ambulance.

METHODS

In this study, the literature review of heat stress related to the effects of global climate change on occupational health was conducted from June to July 2018 using the official publications “PubMed,” “CDC,” and “WHO” and the written sources in this issue.

Temperature and Physiological Effect

Deaths due to high temperatures in the United States cause almost the same amount of deaths as natural disasters such as earthquakes, lightning strikes, and storms. For this reason, high-temperature fluctuations due to global climate change are considered “silent killers” (Jacklitsch et al., 2016), as they do not leave devastating traces behind like any other natural disasters. While even people in resting circumstances are losing their lives due to high

temperatures, it would not be wrong to say that workers who are working with physical strength in unsupervised conditions and not provided with adequate measures are seriously endangered by extreme temperatures.

For the human body to function properly, it is necessary to keep the body temperature constant. The temperature of the brain, the thorax, the abdomen, which is called the core temperature, is not the same thing as the surface temperature. Core temperature is $37 \pm 1^{\circ}\text{C}$, whereas the surface temperature is $2\text{--}4^{\circ}\text{C}$ lower (Marchetti et al., 2016). The body uses a thermoregulation mechanism to keep its temperature persistent. In this mechanism, the hypothalamus works as a thermoregulation center, while the frontal lobe reduces the body temperature, and the posterior lobe works to raise the body temperature together with peripheral vessels, striated muscles, and thermoreceptors. The human body can survive in environments at a temperature of 10°C below the core temperature but cannot survive in environments at the temperature of 5°C above the core temperature (Marchetti et al., 2016). For this reason, convection, conduction, radiation, and evaporation develops in the body to stabilize the rising body temperature.

Convection: It is defined as the temperature change between the skin and the ambient air surrounding the skin. If the ambient temperature is larger than 35°C , body temperature increases. If the ambient air temperature is below 35°C , body temperature decreases.

Conductivity: The temperature difference between the skin and the surface directly contacting it. In some special CBRN (Chemical, Biological, Radiological and Nuclear Threats) uniforms, furnace work uniforms, liquid circulation special work uniforms, cooling is done with this logic.

Radiation: Heat is displaced by radiation. The body's thermal radiation is usually persistent.

Evaporation: It is defined as heat loss caused by sweat evaporation from the body. The amount of relative humidity in the environment affects the amount of maximum perspiration (Jacklitsch et al., 2016).

Severe physiological changes transpire when the ambient temperature reaches or exceeds the core temperature (Kjellstro et al., 2009; Parsons, 2003). When the body temperature exceeds 38°C , a decrease in physical and mental abilities is observed, a heat stroke when the temperature exceeds 39°C , damage in large organs, loss of consciousness and death when it exceeds $40,6^{\circ}\text{C}$ (Marchetti et al., 2016).

The sun exposure in the working environment, the humidity and the temperature of the environment, the worker's uniform, the body surface area, and the worker's job are directly influential in the degree of influence from temperature.

Thermal Comfort

The heat, humidity, airflow conditions are called thermal comfort which is substantial for the most of the workers' relaxation in the working environment. The temperature range of the working environment isn't the only criteria that determines thermal comfort (CDC, 2017), although the temperature range that most people feel comfortable is between $20\text{--}26^{\circ}\text{C}$. In addition to temperature, humidity is another important criterion. While the very low humidity in the environment can dehydrate the body surface, evaporation does not occur sufficiently

under very high humidity conditions. Therefore, the body cannot sweat, and the body temperature cannot be adjusted, it can cause “heat stress” and “hot impact.” Ideally, the relative humidity in the working environment should be between 30-80% accordingly the weight of the work done, the season characteristics, the temperature of the environment. The airflow rate is an important factor that causes the exchange of the temperature between the environment and the workers, and the removal of pollutants such as odors and dust in the environment. NIOSH recommends a working airflow rate of 20-150 mm/sec (CDC, 2017; Jacklitsch et al., 2016).

Radiant heat is one of the most important factors that affect working ambient temperature. Radiant heat is electromagnetic waves emitted by radiation from heat and light sources and their heat effect. The solar rays also affect the thermal comfort as solar radiation as well as artificial materials like raw materials produced in the working environment such as glass, molten metal.

Wet Bulb Globe Temperature (WBGT) value is used to determine thermal comfort (Jacklitsch et al., 2016). The WBGT value is the heat load the worker is exposed to in the working environment. In other words, it is the effective temperature that is felt. In other words, it is the effective temperature that is felt. This value is the result of measuring the dry bulb temperature, radiant temperature, and wet bulb temperature in the environment using a formula.

A 1% increase in body temperature leads to a 10% increase in metabolism rate, an increase in the number of pulses, a very slight decrease in systemic blood pressure, and an increase in fluid loss (Yenen, 2017). In addition to these physiological changes, there are risky situations that threaten job security such as careful reduction, fatigue, exhaustion, a decrease in mental functions. Many studies indicate that temperature increase affects the emotional state, prolongs the duration of the reaction, and reduces mental activity in a variety of complex tasks (Lenzuni et al., 2014; Fisk, 2000). While the effective temperature of 29°C leads to a 5% decrease in the work efficiency of the worker, the decrease reaches 30% at 32°C effective temperature.

Heat Stress

The net heat load resulting from the combined contribution of the worker’s metabolism, environmental factors, and the working clothing is defined as heat stress (Jacklitsch et al., 2016). This load causes an increase in body temperature by heat storage in the body, which triggers physiological changes. Due to this situation, the respiratory and cardiovascular system may be affected, resulting in acute or chronic insufficiency due to muscle destruction and dehydration (Hansen et al., 2008; Kjellstrom et al., 2010; Blois et al., 2015).

If the heat stress is not prevented, meaning the worker is not taken to rest, if the liquid intake is not provided, and if the person is not cooled, hot cramps, hot syncope and finally heat strokes can be expected. In heat stress, the main factor that determines the answer of the person is the acclimatization, meaning adaptation to work. If the worker is not in acclimatization, he is more affected by the temperature change. If the worker is in acclimatization, the temperature he can tolerate is higher, the duration of endurance is longer without strain. For workers to get the least damage from the heat, NIOSH and ACGIH

(Association Advancing Occupational and Environmental Health) regulated workers' working and rest periods according to ambient temperatures (Table 1).

Heat cramps: Basic skeletal muscle cramps is seen because of lack of water and salt replacement lost during perspiration.

Heat syncope: There is an enlargement to cool the body in the peripheral superficial veins, where the water and the salt lost by sweating are not replaced, and the heat exposure continues. This vasodilatation causes blood pressure in the brain to drop and temporary loss of consciousness.

Heat stroke: Working in a hot environment with physical power can increase body heat production from 1 kcal/min to 20 kcal/min. This means that the core temperature increases by 1°C every 5 to 7 minutes (Marchetti, 2016). When exposed to high temperature and moisture for long periods of time, the body uses all means to lost heat. The method of losing most heat is the perspiration. Despite the rising body temperature, sweating on the body may not be enough due to intense moisture in the environment, or perspiration stops because sweat is not replaced. In this case, while the body temperature is above 40°C/104°F the activity of the nervous system over the thermoregulation ceases to exist, and uncontrolled temperature increase and significant tissue damage and death due to this increase can be seen (rhabdomyolysis, thrombocytopenia, coagulopathy and multi-organ failure) (Nag et al., 2009; Parsons 2014). A form of hyperthermia associated with a systemic inflammatory response leading to a syndrome of multi-organ dysfunction in which encephalopathy predominates (Bouchama and Knochel, 2002).

With the global climate change, especially for the workers working in daylight, the risk of heat stress and other heat cramps, syncope and heat stroke risks are increasing, and it is expected that this risk will be higher if the precautions aren't taken (Kjellstrom et al., 2016).

Table 1. NIOSH and ACGIH recommended working/rest periods in hot environment

Recommended work/rest periods	Work load weight*		
	Heavy	Medium	Light
	Environment Temperature (°C)		
Continuous working	25	26.7	30
75% working 25% rest (for every hour)	25.9	28	30.6
50% work 50% rest (for every hour)	27.9	29.4	31.4
25% working 75% rest (for every hour)	30	31.1	32.2

*: Work Load Weight Assessment: Light jobs: 200 kcal/hour (Example: Writing-like office work), medium jobs: 200-350 kcal /heavy work :> 350 kcal/h (Example: digging works).

Studies in various countries in the world (Table 2) show that extreme heat at work can cause deaths, heat exhaustion, major organ damage, job accidents, and changes the emotional state and attention resulting in a decrease in performance and economic loss.

In a study conducted in Puerto Rico between 2012 and 2013, it is discovered that the highest death rate was recorded between May and October when the death rates within 2 years were compared. The risk of life loss because of illnesses like stroke (brain hemorrhages, clots, paralysis), hypertension has increased between 2 and 3 times in the 2012-2013 Fall in comparison to the 2009-2010 Fall (Mendez Lazaro et al., 2016). In a study conducted by OSHA between 2012 and 2013, 20 workers who had died or suffered from overheating were

examined and one of them had died and the others had been exposed to high temperature related illnesses.

More than half of the working hours of workers besides home workers, especially farmers and construction workers, are spent outside. Naturally, the changes in climate characteristics are affecting/will affect the health of this working group, as well as occupational health and safety.

In Paris in 2003, it was seen that most of the women lost their lives because of extreme temperature fluctuations were in high age group, and the males were included in the working group between the ages of 25-64 (Pachauri et al., 2014; Robine et al., 2008). Outside workers will be exposed to high temperatures, radiation, chemical substances and it will threaten the occupational health, mainly because of climate change. In a study conducted by NIOSH, 423 workers lost their lives due to high temperatures between 1992 and 2006, and 102 (24%) of them have been working in forestry, agriculture, fishing, hunting fields (CDC, 2008).

Table 2. Situations that develop because of exposure to high heats in workplaces

Effect	Research Area	Researchers
Heat Stroke	South African Mine Workers, US Agricultural workers, China, India, Qatar and other countries	Tustin et al., 2018; Gibson and Pattison 2014; Nag and Nag, 2009; Grandjean and Grandjean 2007;
Unusual severe heat stroke, heat exhaustion	Some hot workplaces in China, India, England, runners in US and Brasil, footballers in US	Nag and Nag, 2009; Parsons 2014; Zhao et al., 2009; WHO, 2014; Pachauri et al., 2014; Watkins et al., 2018; De Martini et al., 2014; Castro et al., 2018; Kerr et al., 2014.
Kidney damage, Major organ damage	US sugar workers, migrant construction workers in Qatar, agricultural workers in Cameroon,	Garcia Trabanino et al., 2005; Kjellstrom et al., 2010; Tawatsupa et al., 2012; Wesselling et al., 2013, Ekiti et al., 2018
Heat-related accidents	Europe, Thailand	Ramsey et al., 1983; Tawatsupa et al., 2013
Behavioral and psychological changes decrease in mental functions	South African miners, Australian farmers, student children in Thailand, Cameroon	Tawatsupa et al., 2010; Berry et al., 2010; Dapi et al., 2010
Decrease in working capacity, economic loss, migration	India, USA, South Africa	Dell et al., 2009; Burke et al., 2015; Kjellstrom, 2016; Kjellstrom, 2011; Kjellstrom, 2009

(Kjellstrom T., Briggs D., Freyberg C., Lemke B., Otto M., Hyatt O. Heat, Human Performance, and Occupational Health: A Key Issue for the Assessment of Global Climate Change Annu. Rev. Public Health 2016. 37:97-112).

In a study conducted by Eisenberg and Methner (2018), which examined the heat stress conditions of the park workers, didn't detect dehydration and muscle destruction while the decrease in the working efficiency of the people, the increase in the pulse was recorded. Nag and Nag (2009) recorded the most intense heat stress findings (e.g., headache, palpitations, systolic pressure, apathy etc.) in the rock crushing workers working outside among workers working in ceramic, mine (iron), and rock breaking. Tawatsupa et al., (2012) found that, in Thailand, labor-intensive workers were significantly more likely to experience heat stress than workers in the office and that they were experiencing kidney dysfunction due to heat stress, even more in 2009 than in 2005. Gracia Trabanino et al., (2005) emphasized that chronic renal failure and proteinuria in agricultural workers in El Salvador may be due to heat stress. Ekiti et al., (2018) found parallel results in a study conducted by agricultural workers in Cameroon. In a study conducted by Tustin et al., (2018), 78.6% of 25 outside workers in the United States between 2011 and 2016 were exposed to fatal heat stress in acclimatization.

Beck et al., (2018) found that WBGT and UV exposures of workers engaged in gardening work were above the legal limits.

It is estimated that in addition to direct health problems of global climate change such as the heat stress, in 2030-2050, particularly in South East Asia and the Ecuadorian belt countries, a decrease in working capacity and a 50% loss in production due to a temperature increase of 2°C is reported (Kjellstrom et al., 2013). In another study, a modeling study in Southeast Asia has shown that in 2050 more than half of the working hours in the afternoon will be lost due to the greater need for rest breaks. It is estimated that global gross national income will decrease by 23% in the 2100s due to shortening of working hours, reduced work efficiency and other climate-related problems (Kjellstrom et al., 2016).

It is claimed that labor productivity losses will occur in the whole Aegean and Mediterranean coasts in the south of İzmir, and 1% of the losses in the Central Anatolian Region can reach to 7-8% (Altinsoy and Yıldırım, 2013). In a study conducted in our country, a 2001-2050 projection connected to global warming has been made with the labor productivity loss between 1970-2000, and while there is a loss of productivity in the range of 3-18% in İzmir, Aydın, Mersin, and Adana in the past, losses are predicted to rise to 25% in the future.

CONCLUSION

Global climate change is a threat to occupational health due to temperature rise, humidity and extreme warming. In terms of occupational health and safety, the following measures will help to reduce the risk of heat stress and reduce the threat of occupational health and safety; adapting to the NIOSH recommended study/rest periods, taking a 250cc (at a temperature below 15°C) fluid every 20 minutes, supporting workers with athletic liquids in case of extreme perspiration, no alcohol in hot weather, wearing air-permeable thin clothes, the presence of a radio on their side, carrying out an air conditioning which can provide thermal comfort in indoor environments, determining working hours not only by the effect of sunlight but also by the temperature of the air for those who work outside for the following years, and frequent control of WBGT values.

Chapter 271

PHYSICAL ACTIVITY IN WOMEN

Asuman Saltan*

Therapy and Rehabilitation, Yalova University, Yalova, Turkey

ABSTRACT

Intentional physical activity has become necessary with today's evolving technology. However, individuals need a routine in their lives. Individuals are able to complete a lot of work in their daily lives using technology, but this increases their sitting time. This situation emerges into a sedentary lifestyle. There is a negative relationship between sedentary lifestyle and physical activity. As sitting time increases, physical activity decreases. This situation differs between the genders. One reason for this is that women are still an influential value to society, culture, and the economy. Therefore, women and physical activity need to be examined even in today's conditions.

When women perform physical activity, due to physiological structure, menstruation, pregnancy, hormones, emotional state changes, elastic structures, daily life activities, etc. many factors are involved. For this reason, physical activity in women can have different results at different times. In studies, the tendency toward sedentary behaviors of women are higher than that of men. This section includes evidence-based information on the implementation and effects of physical activity in women.

Keywords: exercise, physical, women, sedentary lifestyle

INTRODUCTION

Human survival depended on being physically active and talented in ancient times. People had to live a nomadic lifestyle to meet basic needs such as food and shelter. Thus, they frequently ran, jumped, fought, and walked long distances, thereby performing excessive physical activities. After many centuries, a decrease in physical activity rates occurred. Although the number of cultural and social classes has decreased compared to the past,

* Corresponding Author's Email: fzt_asuman@yahoo.com.tr.

individuals have begun to be inactive after the developments in technology and industry (Brown, 2016).

Today, the definition of physical activity has changed. Physical activity is now defined as entire body movements during which muscles work with a level of energy that is higher than the metabolism relaxation level. This definition includes four headings: 1. Physical activities during leisure time, 2. Physical activities in the workplace, 3. Physical activities during housework, and 4. Physical activities in society (Brown, 2016; Timperio, 2015).

This classification may vary by country. For example, Brazilian public health studies report that physical activities at home or in the workplace should not be calculated. In Latin America, upper limits are exceeded when physical activities at home and in the workplace are calculated. Therefore, physical activities are categorized into two groups: leisure time activities and social physical activities. These differences between countries are important and should be taken into consideration during academic studies. In particular, information should be obtained from the relevant public health departments regarding the definitions of physical activity (Brown, 2016; Timperio, 2015).

Physical inactivity is a life-threatening factor around the world according to the World Health Organization (WHO) that particularly affects women. Approximately 3.2 million people die because of physical inactivity every year. Regular physical activity and exercise protects health and physical fitness and prevents many health problems. Previous studies report strong effects of regular and evidence-based physical activities and exercises on health (Arslan, 2016; Brown, 2016; Timperio, 2015).

Women's health state is dynamic because their hormonal levels are dynamic. Changes in the osseous-muscular organs in non-disease periods such as menstruation, pregnancy, or menopause affect women's health state and quality of life. Thus, the target level of physical activity varies by the phase of the woman's life. In addition, the effect of sociocultural and environmental factors makes women's daily lives complicated (Arslan, 2016; Brown, 2016; Timperio, 2015; Cooke, 2017). This paper aims to reveal the details on the relationship between physical activity and women's health.

EXERCISE AND BONE HEALTH IN WOMEN

Bone health plays an important role in health and the quality of life. Bone tissue is home to minerals in addition to its functions including preventing injuries, protecting bodies, and moving. Thus, it contributes to the normal functions of other organs (from regulating the functionality of endocrine organs to hematopoiesis). An unhealthy bone may lead to breaks and functional losses, which result in disability. This may lead to undesired results including functional dependency and premature death. Osteoporosis is a bone health issue widely observed in women. Many factors affecting bone strength such as changes in bone tissue, decreases in bone density, and changes in bone architecture emerge during osteoporosis. As a result, bones can break easily. For example, one in every two Caucasian women is diagnosed with osteoporosis and osteoporotic fractures are widely observed (Xu, 2016; Zhou, 2014). Although one in every five men also experience osteoporotic fractures, women are at greater risk during their lifetime. Postmenopausal women have increased expenses for synthetic drugs used in the treatment of their higher osteoporosis prevalence. Expenses for elderly

women in England are expected to reach 25.3 million dollars by the year 2025 (Herrmann, 2012; Xu, 2016). Thus, an increase in non-pharmacological interventions is desirable. Exercise prevents breaks and falls in postmenopausal and elderly women, reduces or stabilizes bone loss in middle-aged women, and increases bone density in girls. The WHO, American Collage of Sport Medicine (ACSM), National Institutes of Health (NIH), and National Osteoporosis Foundation (NOF) provide suggestions for the treatment and prevention of osteoporosis. However, these are general suggestions that are not valid for specific age groups. High quality systematic reviews and meta-analyses suggest that exercises done for bone health of women from diverse age groups have positive effects (Xu, 2016).

EFFECT OF EXERCISE ON GIRLS

School practices consisting of short-term plyometric exercises are adequate for the bone health of girls. Exercise programs for 60 minutes or more three days a week or 10- to 20-minute programs performed daily for 12 months or longer are effective for bone development. These programs will be particularly useful for girls with precocious puberty. Awareness should be raised in schools to enable young girls to have healthy bone development, and emphasis should be placed on the effect of school-based exercise programs on bones (Ubago-Guisado, 2015; Xu, 2016).

EFFECT OF EXERCISE ON PREMENOPAUSAL WOMEN

Studies show that regular physical activities have a limited effect on the bones of premenopausal women. However, regular exercises have an effect on the femur neck, lumbar vertebra, and trochanter. In this period, the aim is not to increase bone strength as in girls, but to protect strength and prevent it from decreasing. Resistance exercises tolerated or performed by individuals with moderate to high effects are preferred for bone health during this period. Exercises performed 30- to 60-minutes at least three days a week for 10 months or longer are effective for maintaining bone health in premenopausal women (Xu, 2016).

Home or office exercises are sought for women who do not have enough time for traditional exercises due to familial matters or workload (Xu, 2016). Short-term, high-volume vertical jumping or hopping performed in 1 to 5 sets of 10 to 20 repetitions at 8- to 15-second intervals at least three times a week for six months are recommended (Xu, 2016; Farr, 2013).

EFFECT OF EXERCISE ON ELDERLY POSTMENOPAUSAL WOMEN

Because the prevalence of osteoporosis is higher in the postmenopausal period, the importance of exercises for bone health remains throughout aging. Combined exercise methods are frequently recommended in this period. Exercises lasting for 30- to 60-minutes for a minimum of three days a week for more than 10 months are recommended. Recommended exercises include running, steps, plyometric exercises, jogging forward or

backward, etc. Performing these exercises together protects the structure of bone tissue (Xu, 2016; Chastin, 2014).

EXERCISE IN THE PREGNANCY PERIOD

Many women hesitate to perform exercises during the pregnancy period. Physiotherapists recommend women who were physically active before pregnancy reduce their activity levels. However, exercises have been optimized for pregnant women, as resources from the last 30 years show. Today, physically active pregnant women perform their activities in the same way as they did before pregnancy. Even those who were not active before pregnancy tend to increase their physical activities during pregnancy (Bredin, 2013).

In the past, the primary goal was to protect the fetus and the mother. At that time, people thought that the fetus could be harmed by several factors such as energy substrates or increased body temperatures in addition to the increased oxygen required by the working muscles of the mother. Furthermore, performing too much exercise during the pregnancy period was considered risky because it may increase the likelihood of injuring the lower back or the musculoskeletal system, such as chronic fatigue or hypoglycemia. Therefore, many physicians suggested reducing physical activities during pregnancy (Bredin, 2013).

Systematic reviews between 1982 and 2009 show that exercises performed by pregnant women with no contraindications are only slightly risky (Bredin, 2013). Uterine contractions that can last for 72 hours are the leading side effect. However, previous studies show that fetal bradycardia is the most severe side effect. On the other hand, leg cramps, fatigue, and weakness are defined as temporary problems rather than side effects (Bredin, 2013).

If women want to exercise during pregnancy, a health care professional should accompany them. Health care professionals should examine the general health of the mother before preparing the exercise program. They should first eliminate the risks that have side effects. Then, they should prepare a program that will last at least 30 minutes in a day, three days a week during the second trimester with a level that is 50-70% of the maximum heart rate. Water activities such as steady cycling, walking, and swimming are among recommended exercises (Bredin, 2013; PAR-Q+ Collaboration (PAR-Q+), 2011; PAR-Q+ Collaboration (ePARmed-X+), 2011). Bredin et al. (2013) suggested professionals design a flow chart similar to Figure 1.

Medium-level exercises have no side effects or they have only slight side effects for healthy mothers or their children if this is the mothers' first pregnancy and there are no complications. Being inactive before pregnancy is not a reason for not doing exercise during pregnancy. If the examination conducted by a health care professional shows a pregnant woman is at low risk, there is also a low likelihood for the emergence of side effects from the exercises. A screening process should certainly be conducted before calculating the rate of physical activity or starting any activity program (Bredin, 2013; PAR-Q+ Collaboration (PAR-Q+), 2011; PAR-Q+ Collaboration (ePARmed-X+), 2011).

Although regular physical activity is recommended during pregnancy, pregnant women consider that loss of balance and joint or connective tissue traumas may occur. They sometimes avoid performing an activity for fear of causing trauma to the fetus. The most

significant point here is that pregnant women should exercise with a health care professional (such as a physiotherapist) (Bredin, 2013).

Figure 1. Professionals design for assessing the risk of adverse events during physical activity in pregnant women at clinic (Bredin, 2013).

Thus, the question “Does the emergence of side effects from regular physical activity among inactive or active women during pregnancy differ by fetus or mothers’ themselves?” which was specified in the previous literature is still valid, and there is a need for further research. This study implies that pregnant women with no contraindications should be directed to medium-level activities. The relevant literature does not provide precise information about the level of physical activity acceptable during the pregnancy period. For example, whether sportswomen can continue performing their activities at the same intensity level during pregnancy is still unknown (Bredin, 2013; Cooke, 2017).

Studies conducted between 1950 and 2015 indicate that exercise has no side effects. A study conducted in the 1960s reported that being inactive during the pregnancy might lead to negative outcomes such as premature labor, miscarriage, or placental abruption (Bredin, 2013). The application method of exercises is not clear during the pregnancy of sportswomen with high levels of physical activity (Bredin, 2013; Cooke, 2017). Future studies on exercise during pregnancy should question if women's exercise level depends on factors such as education and socioeconomic levels. However, exercise during pregnancy has positive physical and psychological effects. Women's physical activity level before the pregnancy and the sports played before pregnancy should be questioned. The upper limit of the exercise level during pregnancy is still unknown for women who play sports or have high levels of physical activity.

WOMEN AND SPORTS

Previous studies report an increase in the rate of women who play sports. The Lancet Series published in 2016 found a relationship between public health and physical activity starting from the 2012 London Olympics to the 2016 Rio Olympics. In the 2020 agenda of the International Olympic Committee, a participation rate of 50% for women and girls in sports activities is targeted (Cooke, 2017). Participation of women in the Olympics should be encouraged because men fill the open positions because they participate in more sports than women do (Sallis, 2016). Interestingly, the universal estimations of the WHO report the rate of physical activity except sports among women is 35% higher than among men (WHO Global Health Observatory, 2018). Here, the definition and types of physical activity should be closely examined. In addition to leisure time activities, workplace activities or physical activities performed during travel should be considered while preparing the reports. Thus, women may be considered more physically active than men, particularly in countries with low-income levels because women have higher workloads than men do. However, the mean score for women's leisure time activity was 13.7 minutes/day whereas this rate was 25.3 minutes/day among men in low- or middle-income countries (Cooke, 2017).

Participation in sports increases leisure time activities among women. It not only improves physical health, but also mental health and social participation. The UN Inter-Agency Task Force on Sport for Development and Peace reported that as the number of people participating in sports activities increases, the number of physically active individuals also increases. Additionally, the rates of education, maintenance of peace, reduction of trauma, and economic development also increase (Brown, 2016; Cooke, 2017).

The rate of participating in physical activities among different countries varies by gender, age, disability, education level, and socioeconomic status. However, while sports are the fastest way to enable individuals to lead an active life, there is no specific method to increase participation in sports activities. This is apparently due to the presence of different methods performed during the activities (Cooke, 2017). Gender differences in sports participation occur in low- or middle-income countries due to several factors such as cultural/religious values and the role of women in the society. For example, countries such as Qatar, Saudi Arabia, and Brunei had teams of women who participated in the 2012 Summer Olympics for the first time dressing in accordance with their beliefs (Brown, 2016; Cooke, 2017).

WOMEN AND E-HEALTH

Previous studies show physical activity is a highly modifiable health behavior. The WHO suggests 150-minutes of medium-level aerobic activities per week. Although regular physical activity is useful for many conditions from hypertension to depression, the rate of physical activity among women ranges from 3% to 14% (Reed, 2015).

Modern life has placed many additional burdens on women who work outside the home. Women try to exist in every facet of life including the workplace, home, and social areas. High levels of physical activity do not occur during childcare, cooking, gardening, and house cleaning. Thus, women's participation rate in physical activities is 22 to 33% lower than men's is. In low-income families, women even tend to find a second job. Many women report that they too busy to spare time for sports. In this case, e-health services promote physical activities and facilitate their follow-up (Qualcomm Wireless Reach, 2014; Reed, 2015; World Health Organization, 2014).

In a general sense, e-health service is the use of emergency information and communication technology. Previous studies found that e-health services are effective for fitness, nutritional practices, weight loss and conservation, management of chronic diseases and medications, psychological factors, health risks, and health care expenses. E-health services have allowed an increase in the rate of physical activities among women and raised awareness of health interventions such as quality of life, blood pressure, and glucose levels. E-health allows individuals to see their electronic health records when required (Qualcomm Wireless Reach, 2014; Reed, 2015; World Health Organization, 2014).

E-health services in developing countries include age, education level, number of children, work status (part time, full time, or casual work), country, income level, physical activity level, type of e-health service (short message or online web form, virtual care programs, phone or smart phone applications, or gathering data from wearable physical activity measurement instruments), and intervention mode (wearable, telemedicine, mobile devices, health informatics, or multi-single component). However, further studies are required to determine which e-health service is most effective and how it increases physical activities because e-health services have not been included in the relevant literature, yet.

Chapter 272

THE ENHANCED RECOVERY AFTER SURGERY PROTOCOL AND THE ROLE OF SURGICAL NURSES

*Selda Mert Boğa**

Vocational School of Health Services, Kocaeli University,
Kocaeli, Turkey

ABSTRACT

The protocols were established to reduce the length of hospital stay of patients because the healing of patients is negatively affected due to long hospitalization as a result of traditional practices. Enhanced Recovery After Surgery Protocol (ERAS) is a evidence-based care model which was designed to accelerate post-operative healing and provide recommendations for patient care applications to be performed before, during and after the surgery. In the protocol that requires a multidisciplinary approach, surgical nurses play an active role at each stage of the process. Therefore, surgical nurses should be aware of their dependent and independent roles in the ERAS protocol, reflect them in the care of the patient, follow the current publications about the protocol and be open to develop. In this chapter, the ERAS protocol components, recommendations and the role of the nurses in the surgical process are emphasized.

Keywords: enhanced recovery after surgery protocol, fast track surgery, surgical nurse

INTRODUCTION

It is known that healing after surgery can be accelerated and surgery-related deaths can be reduced by the current approach for treatment and care and evidence-based applications in surgery. One of the evidence-based applications in this direction is the Enhanced Recovery After Surgery (ERAS) or Fast Track Surgery (FTS) protocol developed by the ERAS Society (Abdikarim et al. 2015). The ERAS program is evidenced-based protocols which were designed to standardize and optimize perioperative medical care in order to reduce surgical trauma, perioperative physiological stress and organ dysfunction related to elective

procedures. In addition, improved outcomes, decreased hospital length of stay and faster patient recovery to normal life are expected to be obtained. Other advantages of this philosophy are the reduction of clinical complications and the health costs together with and increase of patient satisfaction (Jimenez et al. 2014, p.487).

The ERAS protocol is a combination of evidence based findings which works synergistically to accelerate the post-surgical recovery period, contains recommendations for patient care at different stages of the operation and requires multidisciplinary (surgeons, anesthetists, nurses, physiotherapists and dietitians) approaches (Kehlet and Wilmore 2005, Varadhan et al. 2010, Demirhan and Pınar 2014, Neville et al. 2014, Karen et al. 2015, Çilingir and Candaş 2017, Watson 2017).

The main goals of the protocol is to reduce postoperative morbidity and mortality, to reduce the duration and cost of hospital stay and to affect patients' perceptions about surgery positively by reducing the reaction of the body to surgical stress via optimizing perioperative nutritional status and promoting analgesia without opioids and postoperative early nutrition (Ljungqvist et al. 2017, Karen et al. 2015, Thorell et al. 2016, Çilingir and Candaş 2017, Yang et al. 2017, Aksoy et al. 2018, Li et al. 2018, Persico et al. 2018). In addition, it is aimed to minimize the pain, complications and functional disorders that may occur after discharging, with the ERAS protocol (Jimenez et al. 2014, Hübner et al. 2015, Çilingir and Candaş 2017). The success of the ERAS protocol depends on the preferably complete fulfillment of the protocol; nurses are an important part of this program. The components and recommendations of the ERAS protocol and the role of surgical nurses before, during and after the surgery are described below.

PREOPERATIVE PERIOD

Preadmission Information, Education and Counselling

Perioperative education for patients and their family members is essential for successful navigation through the surgical experience. There are limited studies that address the benefits of education before surgery; however, evidences show that preoperative teaching conducted before hospital admission is mostly successful. Ronco et al. (2012) found that patient information provided before surgery and reviewed after admission is more effective than information solely received before surgery. After the plan for surgery is confirmed, the patient should begin to receive information from the medical team. The education that the patient receives in the office will set the tone for the surgical experience. The goal of an effective patient education plan is to inform the patient and his or her family members about what to expect during each phase of the experience. Patients often worry about how long they will be hospitalized, types of dressings, driving restrictions, and when they can return to work and household activities, among other things. The goal of the education is to address these stresses and to help patients adequately prepare for and anticipate needs during recovery. A comprehensive education plan helps patients and caregivers engage in the process to prepare for the surgical experience. Including caregivers in the education process helps minimize stress and provides patients and their family members with more realistic expectations to better prepare for returning to home (Karen et al. 2015).

Optimisation of the Patient's Health before Surgery

It is emphasized that smoking and alcohol use should be quit four weeks before surgery. Alcohol users are at high risk for wound healing, cardiopulmonary function and bleeding; mortality rates are 2-3 times higher in alcohol users (Gustafsson et al. 2013). Pulmonary function and wound site complications are more frequent in smokers (Tunç Tuna and Kurşun 2018).

Preoperative Colon Cleansing

Mechanical colon cleansing is traditionally thought to alleviate the severity of sepsis in the event of anastomotic leakage. However, recent studies have shown that mechanical intestinal cleansing which was started to be applied in 1887, caused stress, dehydration, electrolyte imbalance, long-lasting hunger and delayed normalization of bowel functions; new methods are used instead of this application (Aksoy et al. 2018).

Preoperative Fasting and Carbohydrate Therapy

Stopping oral solid and liquid food intake as from the midnight before elective surgery applications, has been started to apply to reduce the possibility of pulmonary aspiration; it is applied daily as a routine today. However, it has been reported that there is a decrease in the well-being of the patient and some metabolic adversities, especially post-operative insulin resistance after this application (Ersoy and Gündoğdu 2007; Demirhan and Pınar 2014). Today, the accepted fasting protocol is to consume clear liquid food for up to two hours before surgery and to consume solid foods for up to six hours before surgery (Ersoy and Gündoğdu 2007; Yang et al. 2017). In addition, it has been stated that giving 800 ml of carbohydrate fluid until midnight before surgery and giving 400 ml of carbohydrate fluid until 2-3 hours before surgery, accelerate healing after surgery, reduces insulin resistance and significantly shortens the length of hospital stay (Ersoy and Gündoğdu 2007, Demirhan and Gündoğdu 2007, Demirhan and Pınar 2014, Aksoy et al. 2018). It has been suggested that diabetic drugs can be given in combination with carbohydrate therapy in diabetic patients (Gustafsson et al. 2013). In this period, nurses should ensure fasting of patients in the pre-operative period and apply medications.

Tromboembolism Prophylaxis

In patients having symptoms, it has been foreseen to use it in appropriate doses (Ersoy and Gündoğdu 2007). In addition, thromboembolism preventive compression socks have been recommended (Demirhan and Pınar 2014).

Antimicrobial Prophylaxis

Antibiotic prophylaxis is used to reduce wound infections after surgery. The antibiotics affecting both aerobic and anaerobic organisms should be administered only once (30 min) before the surgical incision (Demirhan and Pınar 2014, Yang et al. 2017). It has been recommended to repeat a second dose in prolonged surgery (longer than 3 hours) (Ersoy and Gündoğdu 2007, Demirhan and Pınar 2014).

Premedication

The use of antiarrhythmic drugs, beta blockers and statins is also appropriate if there is an indication for premedication (Aksoy et al. 2018). It has been not recommended to administer long or short-acting sedative drugs before surgery because it will delay the healing after surgery (Gustafsson et al. 2013, Solak-Kabataş and Özbayır, 2016).

INTRAOPERATIVE PERIOD

Anesthesia Protocol

In the ERAS, it is aimed to reduce the surgical stress response. The anesthetic technique should be applied in a way to allow the patient to recover quickly and minimize the opioid effect during the recovery period (Demirhan and Pınar 2014, Solak-Kabataş and Özbayır 2016). The application of the rapid onset and short-acting hypnotic anesthetics, opiates and muscle relaxants shortens the healing period in the postoperative period (Ersoy and Gündoğdu 2007, Demirhan and Pınar 2014). If possible, thoracic epidural analgesia should be used in laparoscopic colon surgery. The application of anesthesia and analgesia via epidural catheters in colorectal surgery reduces insulin resistance, increases motility via preventing sympathetic inhibition of the gastrointestinal tract and makes the use of narcotic analgesics unnecessary (Ersoy and Gündoğdu 2007, Solak-Kabataş and Özbayır 2016).

Selection of Surgical Incisions

The use of transverse or oblique incisions in abdominal surgery can reduce pain and pulmonary risks. A vertical incision can be preferred if adequate vision is achieved. According to the ERAS protocol, it is not a definite binding rule but it is necessary to use the shortest possible time (Demirhan and Pınar 2014).

Nasogastric Intubation

The ERAS protocol has argued the idea that drains, tubes and catheters should be used limitedly and removed immediately after surgery even if they were placed during the

operation (Ersoy and Gündoğdu 2007, Demirhan and Pınar 2014, Aksoy et al. 2018). It has been stated that the use of nasogastric intubation does not alter the rate of bowel function recovery, reduce pulmonary complications and hospital stay or other postoperative complications but it delays oral feeding and increases the incidence of pneumonia, atelectasis and fever (Aksoy et al. 2018).

Use of Drains

Postoperative draining has not been recommended because it may prevent the mobility of the patient (Demirhan and Pınar 2014, Solak-Kabataş and Özbayır 2016). It has also been stated that the use of drains has no effect on anastomotic leaks (Ersoy and Gündoğdu 2007).

Urine Catheter

Bladder catheter should be taken early because of disadvantages such as urinary infection and mobility restriction. However, the probability of urinary retention increases as a result of epidural blockage, it is necessary to keep the catheter as long as the blockage continues (Ersoy and Gündoğdu 2007, Demirhan and Pınar 2014).

Perioperative Fluid Management

In modern fluid therapy, fluid infusion which is enough to keep the patient as hydrated, is accepted as adequate. The hyperhydration in intraoperative and early postoperative periods (especially NaCl containing fluids) has been reported to increase the complication rate and the length of stay in the hospital (Ersoy and Gündoğdu 2007). The fluids (colloids and crystalloids) should be administered at the optimal level thereby monitor the cardiac function of the patients during the operation. It is aimed to decrease the length of hospital stay of patients and to improve gastrointestinal function of patients in a short time (Solak-Kabataş and Özbayır 2016).

Prevention of Intraoperative Hypothermia

Hypothermia that occurs during surgery stimulates sympathetic discharge and metabolic endocrine response, increases bleeding via disrupting clotting balance, causes postoperative dizziness and also increases pain at the incisional site via increasing oxygen consumption. Nowadays, it is recommended to start to warm up before the surgery to reduce the central and peripheral temperature differences of the patients and to ensure normothermia (Aksoy et al. 2018). In the literature, it has been reported that this practice reduces blood loss, wound infection, unwanted cardiac events, patient discomfort, the starting time of intestinal motility and the duration of hospitalization (Alfonsi et al. 2014, Aksoy et al. 2018).

It has been recommended that heaters should be used to prevent hypothermia during surgery; the IV fluids should be above 36°C to maintain the body temperature (Gustafsson et al. 2013, Solak-Kabataş and Özbayır 2016). The heating should be continued until the patient's body temperature increases up to 37°C. Active heating should be stopped when body temperature is above 37°C (TARS 2013). It has also been shown that a 1,90°C decrease in body temperature increases the risk of wound infection and the duration of hospitalization by 20% (Mehta and Barclay 2014). Maintaining body temperature at normal levels is one of the critical components of the care before, during and after surgery. Nurses should prevent the frequency of complications in patients by accurate follow-up of patients' body temperature (Oshvandi et al. 2014).

POSTOPERATIVE PERIOD

Elimination of Nausea and Vomiting after Surgery

Postoperative nausea and vomiting are important determinants of well-being and should be prevented because they limit oral feeding of patients in early period (Ersoy and Gündoğdu 2007). The prevention or reduction of nausea and vomiting can reduce fluid electrolyte imbalance, wound dehiscence, haemorrhage, the risk of aspiration pneumonia, the duration of hospitalization and re-hospitalization rates (Miles et al. 2015). The first strategy to reduce nausea and vomiting after surgery is antiemetic prophylaxis. The second strategy is to avoid the use of general anesthesia, propofol and nitric oxide and to reduce opioid use for reducing nausea and vomiting after surgery (Aksoy et al. 2018).

Stimulation of Gastrointestinal Motility

Stimulating gastrointestinal motility and more importantly, avoiding from the use of agents that adversely affect motility is essential for the maintenance of early enteral feeding (Yang et al. 2017). For this purpose, it has been recommended to use epidural analgesia, to avoid the use of opioids, excessive hydration and to use oral magnesium oxide 2x1 gr/day (Ersoy and Gündoğdu 2007, Demirhan and Pınar 2014).

Postoperative Fluid Intake

Oral fluid intake should be started as early as possible after surgery and patients should be encouraged to consume fluids (Yang et al. 2017). High-energy fluids contribute to the normal healing process because of the protein/carbohydrate in their contents. In addition to vitamins, minerals and trace elements, it is recommended that carbohydrates be prescribed as 150 kJ/100 ml and proteins as 3-6 g/100 ml. Balanced crystalloid solutions such as 0.9% sodium chloride to prevent hyperchloremic acidosis. The dose and application duration of starch solutions should be limited due to side effects such as renal dysfunction and bleeding. The urine output is the first symptom of hemorrhoids after surgery and therefore oliguria

should be evaluated well by nurses. The medical examination of the lungs, neck and veins, heart, abdomen, and extremities provides information about the volume (Aksoy et al. 2018).

Postoperative Analgesia

Optimal control of the pain along with reducing opioid use in surgery as much as possible, is one of the most important components of the ERAS protocol (Aksoy et al. It has been recommended that the postoperative pain control should be performed without the use of opioid analgesics as much as possible because they negatively affect gastrointestinal system, respiratory functions and central nervous system (Solak-Kabataş and Özbayır 2016, Yang et al. 2017).

The long-continued studies on the multimodal analgesic approach proposed by the ERAS protocol have shown that the use of non-steroidal anti-inflammatory (NSAID) drugs (acetaminophen, gabapentin and dexamethasone) reduces pain and minimizes opioid use (Khan et al. 2009, Thorell et al. al. 2017, Aksoy et al. 2018).

Early Removal of Nasogastric Tube, Foley Catheter, and Drainage Tube(s)

All indwelling catheters and tubes will potentially increase the incidence of infection and sepsis, although most ERAS protocols and expert consensus recommend minimizing the use of indwelling catheters and tubes. If medically needed, those inserted catheters and tubes should be removed as soon as medical conditions allow. For patients needing indwelling centralvenous catheterization, the catheter should be removed and replaced in no >1 week or whenever the patient's body temperature escalates (Yang et al. 2017).

Postoperative Nutrition

One of the most important criteria for postoperative well-being and early discharge is early oral feeding (Ersoy and Gündoğdu 2007). Postoperative intravenous fluids should be prematurely cut; oral feeding should be started as soon as possible. Early postoperative oral feeding has been shown to reduce postoperative complications, mortality and the length of hospital stay (Solak-Kabataş and Özbayır 2016). Patients should be encouraged to drink liquid at 2nd hour after surgery and to eat solid food at 4th hour after surgery. Oral nutrition solutions should be provided as a supplement until the maintenance of adequate oral nutrition. Postoperative nutritional support should be continued for at least 8 weeks in patients taking preoperative nutritional support due to their impaired nutritional status (Ersoy and Gündoğdu 2007, Demirhan and Pınar 2014).

Early Mobilisation

Post-operative bed rest is not desirable because it causes to lose muscles, to decrease muscle strength, respiratory function and tissue oxygenation, venous stasis and thromboembolism (Demirhan and Pınar 2014, Yang et al. 2017, Aksoy et al. 2018). According to the ERAS protocol, patients should be kept out of bed for 2 hours on the operation day and for 6 hours a day until the discharge on the following days (Ersoy and Gündoğdu 2007, Khan et al. 2009, Tunç-Tuna and Kurşun 2018). One of the responsibilities of nurses is to help early ambulation (Çam 2015, Tunç-Tuna and Kurşun 2018).

Duration of Hospital Stay and Discharging Criteria

Since the duration of hospital stay is shortened as the primary outcome of the ERAS, planning of discharge should be emphasized both during preoperative patient informing program and hospitalization. A careful and detailed discharge planning should be done to reduce the number of re-applications to the hospital, to improve patient safety and satisfaction (Demirhan and Pınar 2014). Tolerating normal diet well and becoming mobilized adequately by the patient, maintaining sufficient pain control and eliminating intravenous fluid dependency have been stated as discharge criteria (Ersoy and Gündoğdu 2007, Solak-Kabataş and Özbayır 2016).

In the literature, randomized controlled clinical and meta-analysis studies have reported that patients followed-up with the ERAS protocols have shortened total duration of hospital stay and fallen half complications (Adamina et al. 2011, Thorell et al. 2016, Yang et al. 2017, Li et al. 2018, Persico et al. 2018).

Follow-up

Discharged patients should be called by phone 24-48 hours apart; their situation should be got to know. If there is no problem, the patient should be invited on the seventh to tenth days postoperatively to control the wound and remove the sutures (Demirhan and Pınar 2014). The ERAS protocol will come to the fruition via sharing and discussing the data. Thus the protocol will be developed and, if necessary, halting points will be changed (Ersoy and Gündoğdu 2007, Demirhan and Pınar 2014).

The Role of Nurses in Implementation of the Accelerated Healing Protocol after Surgery

Not only surgeons but also anesthesiologists, nurses, and physiotherapists actively participate in the protocol, which is different from traditional approaches, and even patients are included (Karen et al. 2015, Ljungqvist et al. 2017, Aksoy et al. 2018).

Since surgical nursing covers nursing care before, during and after the surgery, it continues from the admission of the patient to the discharge of the patient; nurses play active

roles in every step of the surgical procedure (Demirhan and Pınar 2014, Hübner et al. 2015). The ERAS protocol is one of the current evidence-based approaches to which surgical nurses should adapt (Mitchell 2011, Karen et al. 2015, Çilingir and Candaş 2017). For this reason, surgical nurses should know their dependent and independent roles in the ERAS protocol, use these information in patient care, follow the current publications about the ERAS protocol and be open to develop. Evidence based nursing practices provide quality care in terms of bio-psychosocial health, improve the quality of care and its outcomes, create a difference in clinical practice and patient care outcomes, standardize care, minimize administration errors and increase nurse satisfaction (Karen et al. 2015, Aksoy et al. 2018).

Surgical nurses should continue patient education during the surgical procedure by especially identifying the problems that individuals may experience after discharge with good planning in the preoperative period. The fact that the ERAS is a multidisciplinary approach; the presence of surgical nurses at every step supports this consideration (Karen et al. 2015, Çilingir and Candaş 2017). In this approach, nurses have a key role in fulfilling the somatic and physiological needs of patients. The ERAS protocol is a model which consists of the applications involving nurses' dependent and independent roles. In the ERAS protocol, nurses have a role in psychological support especially for decreasing the stress of patients, restarting normal diet by patients, early mobilization and early rehabilitation of patients as soon as possible (Solak-Kabataş and Özbayır 2016). Nurses are also primarily responsible for the monitoring of the surgical procedure because nurses are health professionals in contact with patients for 24 hours therefore they also primarily responsible for the application and maintenance of the ERAS program (Hübner et al. 2015, Ljungqvist et al. 2017, Watson 2017). According to the literature, it has shown that the surgical nurses use their time more effectively and have lower workload as a result of the application of the ERAS protocol (Bianchini et al. 2014, Hübner et al. 2015, Pędziwiatr et al. 2015, Persico et al. 2018).

Chapter 273

CURRENT APPROACHES TO PREVENT DIABETIC FOOT ULCERS

Ayfer Peker

Health Care Services (Podology), Kocaeli University, Kocaeli, Turkey

ABSTRACT

Diabetes mellitus (DM) is a common metabolic disorder that can cause various complications. According to the literature, the prevalence of diabetes is rapidly increasing both in Turkey and worldwide. DM is an important health issue due to the high costs of healthcare and serious complications that may affect patients in different ways. Diabetic foot ulcer is a major complication of DM. Although highly preventable, diabetic foot ulcer places a mental, physical, social, and economic burden on patients, and it significantly affects their quality of life. Besides longer bed occupancy and higher healthcare costs, diabetic foot ulcer also increases the risk of lower limb amputation and mortality. Almost 12-25% of diabetic patients will suffer from diabetic foot ulcer during their lifetime, and 10-15% of patients admitted with diabetic foot require surgical intervention. The amputation rate in diabetic foot disease throughout Europe was reported as 0.5-0.8%. In the United States, 85% of lower-extremity amputations are preceded by foot ulcers in patients with DM. Evidence-based guidelines for the management of diabetic foot problems have noted that diabetic foot ulcers can be prevented to a great extent through regular foot examinations and proper therapeutic measures. The treatment and care of diabetics require a multidisciplinary approach because of the extensive nature of the problem. Regular diabetic neuropathy assessment, vascular assessment, joint and muscle examination, and walking analysis are thus recommended. Care of the pressure points on the plantar aspect of the foot is also essential to prevent diabetic foot ulcers. The main objective of a healthcare team in the management of a diabetic patient is to achieve metabolic control with an emphasis on health education, and to improve survival and quality of life.

Keywords: diabetic foot ulcers, prevention, podology, podiatry, walking analysis, personal shoes and insoles

INTRODUCTION

Diabetes mellitus (DM) is one of the most common chronic diseases. It is expensive to treat and its complications have a major impact on health expenses. DM was predicted to affect about 171 million people worldwide in 2000; this was predicted to rise to more than 340 million in 2030 (Wild et al., 2004). DM leads to multi faceted complications. Diabetic foot ulceration is one of the common complications related to the disease, and it can result in lower limb amputations (Boulton and Vileikyte, 2000; Reiber, 2001; Dang and Boulton, 2003; Pinzur et al., 2005).

Foot and lower extremity complications have become an increasingly significant public health concern in people with diabetes in both developed and developing countries. Foot problems are the most important and expensive complications of DM. These complications, such as neuropathy, ischemia and diabetic foot ulcers, typically lead to infection and lower extremity amputation. However, it is possible to prevent amputation in diabetic patients. An approach that involves prevention, patient education, staff education, a multidisciplinary diabetic foot team, and foot screening can reduce amputation rates by 49–85% (Stephanie et al., 2007).

The etiological factors for the development of diabetic foot ulcers can be determined in a clinical environment using inexpensive, everyday equipment designed for foot examination. Preventing diabetic foot ulceration is possible through foot screenings which analyze the protective sensation via the Semmes-Weinstein monofilament, as well as vascular (Doppler ultrasound and ankle-brachial blood pressure), orthopedic, dermatological, biomechanical (plantar foot pressure) issues and include a physical examination with a brief history. These measurements, and the findings of the physical examinations, help health providers to categorize patients based on risk and to decide what approach to use. Regular foot care, patient education, glycemic control and quitting smoking are other effective clinical interventions (Stephanie et al., 2007).

ETIOLOGY AND PATHOPHYSIOLOGY OF DIABETIC FOOT ULCERS

The etiology of diabetic foot ulcers usually has many constituents. The most frequent underlying etiologic factors of diabetic foot ulcers are peripheral neuropathy, trauma, foot deformity and high plantar pressures. Peripheral neuropathy plays a central role in most patients: up to 50% of diabetic patients have diabetic peripheral neuropathy and are at risk of developing diabetic foot ulcers. Neuropathy causes an insensitive and deformed foot, often with problems in walking. Walking barefoot and/or in ill-fitting shoes can induce a chronic ulcer in neuropathic people, as can acute trauma. Thickened skin (callus) grows as a result of the abnormal biomechanical loading of foot due to a foot deformity, limited joint mobility, poor-fitting shoes or a loss of sensation. A subcutaneous hemorrhage forms after this abnormal biomechanical loading of the foot. Peripheral vascular problems may result in an ischemic foot ulcer caused by a minor trauma. Symptoms may be absent in patients with neuropathy, ischemia or neuroischemic foot (Frykberg et al., 2000; Boyko et al., 1999, Pecoraro et al., 1990; Armstrong and Lavery 1998; IWGDF Guidelines, 2011).

Most of the risk factors for foot ulceration are also predisposing risk factors for amputation, because foot ulcers are the prime reason for amputation (Pecoraro et al., 1990; Armstrong and Lavery, 1998). Ulcerations can result in limb loss for two reasons. They can lead poor wound healing and to progressive tissue necrosis in the presence of critical ischemia (Armstrong and Lipsky, 2004).

PREVENTION

The prevention of diabetic foot ulcers in diabetic patients is a major clinical goal of healthcare professionals, as foot problems can result in lower extremity amputations. Studies of the causes of amputation show that ulcers lead to 84% of diabetes-related amputations. (Pecoraro et al., 1990). Prophylactic foot care has been shown to be connected with decreased morbidity, lower health costs and a reduced risk of amputation (Pinzur et al., 2005). Approaches that involve the classification of risk factors, as well as patient and family education and podiatric care, have been proven to be cost-effective and to reduce costs (Moreland et al., 2004; Singh et al., 2005; Ragnarson et al., 2004). Proven strategies for prevention of ulceration involve having a *multidisciplinary team approach to foot care, patient screening and follow-up, professional foot care for pre-ulcerative signs (debridement of hyperkeratosis, callus, corn and nails), patient education and therapeutic shoes* (Pecoraro et al., 1990; Dargis et. al., 1999; Apelqvist and Agardh, 1992).

Multidisciplinary Foot Care

Diabetic foot is a frequent problem and leads to high costs. A multidisciplinary foot approach to diabetic foot ulcerations has been shown to reduce the cost of diabetic foot treatment. Studies from around the world show a larger per capita expense for diabetics in general compared to other patients. This high cost is more evident when associated with diabetic foot problems, and is correlated to the length of hospitalization. Multidisciplinary team work with diabetic foot problems has been shown to decrease ulcer and amputation rates, and reduce the costs of the treatment itself (Matricali et al., 2007).

A team of dedicated health care professionals is essential for preventing lower limb amputation. Those responsible for foot care may include a diabetologist, vascular surgeon, podiatrist, orthopedic surgeon, pedorthist, general surgeon, and plastic surgeon. New studies have shown that podiatrists and vascular surgeons are the primary members of the diabetic foot care team. A podiatrist conducts regular screening and offers professional foot care; when a vascular problem appears a vascular surgeon carries out revascularization and after the operation the podiatrist continues to provide foot care (Lee et al., 2010). An ostomy nurse, specialist diabetes nurse, dietician and physical therapist can also participate in the team if required (Lee et al., 2010).

A prospective study noted fewer recurring ulcerations in diabetic foot ulcer patients after the formation of multidisciplinary diabetic foot care teams (Oyibo et al., 2001). Studies from Asia have shown that teamwork and the frequent implementation of preventive diabetic foot protocols strongly decreased the incidence of amputation (Burns et al., 2003). It has also been

proven that the use of multidisciplinary diabetic foot teams including podiatrists reduced amputations by 34% (Connor and Oz, 2004).

Patient Screening and Follow-Up

Patient screening and follow-up means to evaluate the patient's actual risk of developing a diabetic foot ulcer or undergoing amputation using the risk classification system and to carry out reassessments at regular intervals. If there is no peripheral neuropathy, the patient should have a foot examination once a year; if the patient has peripheral neuropathy, they should have a foot examination once every 6 months; if the patient has peripheral neuropathy with peripheral artery disease and/or a foot deformity, they should have a foot examination once every 3-6 months; if the patient has peripheral neuropathy and a history of foot ulcer or a lower-extremity amputation, they should have foot examination once every 1-3 months.(NICE, 2015). A foot examination can be repeated very often (every 1–2 weeks etc.) for high risk patients if there is urgent concern.

Professional Foot Care for Pre-Ulcerative Signs (Debridement of Callus and Nails)

Professional foot care for pre-ulcerative signs means the treatment of any pre-ulcerative sign on the foot. This includes:

- Treatment of calluses;
- Treating blisters and making them safe;
- Treatment of ingrowing or hypertrophic/thick nails;
- Treatment of hemorrhages;
- Treatment protocols for fungal infections.

The usefulness of the treatment of pre-ulcerative signs for preventing foot ulcers has not yet been clearly studied. However, removing calluses has been shown to be beneficial as it decreases plantar pressure which is a significant risk factor for ulcer formation (NICE, 2014; IWGDF, 2015).

Some images of our patients receiving foot care treatment are provided in Figures 1-7.

One randomized controlled study (RCT), one non-RCT and three non-controlled studies showed a dramatically lower rate of recurring foot ulceration in patients who received holistic foot examinations and care compared with those who did not (Dargis et al., 1999; Plank et al., 2003; Hamonet et al., 2010; Marcinia and Chantelau, 1998).

Figure 6. Treatment of an ingrown nail with nail brace.

Figure 7. Treatment of hypertrophic nail

Patient Self-Management Education

Education of the patient and their family should aim to provide the correct information about foot care and how to practice it. It is very important to support the patient in following the advice given. The education should involve how to self-manage their condition, what to do in foot care emergencies, recommendations about shoes, the patient's risk of developing a foot ulcer, and information about DM and blood glucose control. Patient education should be repeated regularly (NICE, 2015).

A diabetic person should practice the following self-management activities in an organized manner:

- Inspection of the feet and the inside of shoes every day;
- Washing the feet every day (drying them carefully especially between the toes);
- Refraining from using chemicals and plasters to treat callus and corns;
- Using balsam oil on the skin;
- Cutting nails straight;
- Monitoring the temperature of the skin on the feet to avoid the recurrence of plantar foot ulcerations (NICE, 2015; IWGDF, 2015).

Therapeutic Footwear

Foot ulcerations/amputations are connected to poorly fitting shoes in diabetic patients so off-loading techniques and different shoes are commonly using for the prevention and treatment of foot problems. Wearing incorrect shoes both indoors and outdoors is a major cause of foot ulcers. Shoes should be adapted to changing biomechanics and to foot deformities. Diabetic people with normal protective sensation can choose their shoes themselves. In people with peripheral neuropathy/ischemia and foot deformities extra attention must be paid when fitting footwear (Pecoraro et al., 1990; Dargis et al., 1999; Apelqvist and Agardh, 1992; Armstrong and Lipsky, 2004).

The patient should be directed to use special diabetic shoes, slippers, socks and insoles at home and when outside. To prevent a recurrent non-plantar ulcer, patients need to use therapeutic shoes, custom-made insoles or a toe orthosis (Chantelau, 1993; IWGDF, 2015).

Patients should use custom-made shoes and insoles to treat a plantar foot ulcer as standard or conventional therapeutic shoes are inadequate for treatment. Traditional half shoes which are designed for off-loading of the forefoot and which only support the heel and midfoot, are unsuitable because of the risk of a midfoot fracture (IWGDF, 2015).

Casual footwear, shoe modifications and toe orthoses can be used to treat and produce off-loading for non-ischemic, non-plantar or under control infection ulcers. Patients should wear well-fitting footwear for a recurrent non-plantar ulcer. Custom-made insoles and shoes, therapeutic shoes and a toe orthosis are required if a foot deformity or a pre-ulcerative sign is present (IWGDF, 2015).

Chapter 274

A REVIEW OF STUDIES ON THE APPLICATION OF COUMARIN AND ITS DERIVATIVES IN PLANTS

Burcu Yuksel*

Kocaeli Vocational School of Health Services, Kocaeli University, Kocaeli, Turkey

ABSTRACT

This chapter summarizes the use of coumarin, a secondary metabolite, and its derivatives in different aspects of plant growth and formation. Coumarin and its derivatives have broad biochemical and pharmacological activities. They also have allelopathic effects on plants. In this chapter, summaries and review of previous research are presented by pointing out significant contributions and effects of coumarin and its derivatives in plant growth and inhibition. Nowadays, the active use of coumarin and its derivatives, which are used as defense elements in several areas such as agriculture, food, cosmetics and medicine, necessitates the clarification of action mechanisms of coumarin. In order to understand these compound's allelopathic and toxic effects completely, it is essential to carry out cytological, genetic, biochemical and physiological tests altogether. In the studies on plants, it is very important to understand the defense mechanisms in plant species that make them resistant to stress conditions in order to minimize yield loss in terms of nutrition and agricultural economics.

Keywords: allelochemical, coumarin, cytotoxicity, genotoxicity, plants

INTRODUCTION

With their broad range and biomass, distribution of plants that constitute the first step of food chain is determined by the biotic (plants that belong to the same species, plants that belong to the different species, animals, bacteria and fungi) and abiotic (temperature, geographical formations, soil composition, water and solar rays) factors. One of these factors,

* Corresponding Author's Email: burcu.yuksel@yahoo.com.

secondary metabolites, are the components that are excreted by the plants. These components affect the choice of the plants' habitats to a large extent. These components' mechanism of action can produce inhibitor effects to a certain extent and may generate physiological, cytotoxic or genetic changes in the organism. Hereditary variations that emerge when these components compete with the organisms' DNA may, in turn, cause decrease in their population or extinction. Also, these components may affect product quantity and quality in a negative way by generating physiological and biochemical damage. The plants appeal to their molecular defense mechanisms in order to minimize or prevent negative effects completely. These components may generate adverse outcomes in the organisms when they are consumed. Coumarin is one of the highly studied secondary metabolites.

Coumarin was purified in its free form for the first time in 1820 by Vogel from the dried sweet-smelling seeds of *Dipteryx odorata* (*Coumarouna odorata*) tree called 'tonka bean,' which grows in South America from the Fabaceae family. In plants, coumarin and coumarin derivatives are commonly found on their own or compositely. Because of their various biological activities, these kinds of compounds are natural compounds that have gained significance in recent years. Coumarin's chemical structure is first explained by Strecker (1867) and Fitting (1870) according to Coffey (1977). Today, apart from the tonka bean, coumarin derivatives are isolated from 600 kinds of plants. Coumarin is found, especially, in Orchidaceae, Leguminosae, Rutaceae, Apiaceae and Lamiaceae families' plants' fruits, leaves, roots, stems and shell sections at a certain rate (Boga, 2005).

Crystal-like, white and solid coumarins are composed of aromatic rings that are fused with condense lactone ring. 1,2-benzopiran, 2H-1-benzopyran-2-one, *cis*-o-coumaric acid lactone and coumarinic anhydride are the other names that are used commonly. Its molecular formula is C₉H₆O₂ and its molecular weight is 146,14 g/mol. While coumarin's melting point is 68-70°C, its boiling point is 297-299°C. Coumarins can be soluble in ethanol, chloroform, diethyl ether and oil, but it is slightly soluble in water. While first class coumarins are isolated from Indian beans, coumarins, which are used for commercially, are synthesized by salicylaldehyde (Yuce, 2006).

Herbal coumarin derivatives have broad biochemical and pharmacological activities. Cinnamic acid and its derivatives, which are the pioneers of coumarin and its derivatives, are the substantial compounds of sweeteners, perfumes, synthetic dye and pharmaceuticals (Bickers et al. 2005). Because of their significant bioactivity power, new types of coumarin derivatives, which have efficient pharmacological value, have been synthesized in recent years. Antibiotic, anti-coagulant, anti-cancer, anti-inflammatory and bacteriostatic effects that are found in coumarin and its derivatives, make them a significant matter in biology and medicine (El-Khatib et al. 2007). They also have antioxidant, vasodilator, anti-inflammatory, immune stimulant, antiallergic and antiviral effects. At the same time, the studies conducted on humans and animals have indicated that coumarins decrease the risk of catching cardiovascular and cancer diseases (Cirico et al. 2006). Although it was used in food industry because of its redolence for a period of time, the studies that were conducted on animals revealed its toxicity and its use was abandoned in this field (Guenther, 1975). These phenolic compounds' toxic aspects are revealed by different researchers. According to the previous research, phenolic compounds like tannic acid, coumarin, vanillin, caffeine and cinnamic aldehyde had mutagenic effects on mammalian cells (Sanyal et al. 1997). High doses of phenolic compounds' genotoxic effects occurred by the mechanisms like DNA intercalation,

DNA topoisomerase II damage, free radical production and key enzyme inhibition (Stopper et al. 2005).

When the topic is approached from plant stress physiology perspective, the agents that are applied on plants generate various changes on plant metabolism. In order to determine physiological and biochemical changes, one has to have knowledge about the transmitter and the target plant. At the same time, knowing these agents' structure and mechanism of action eases the description of morphological, cytological and genetic changes that they cause. For instance, abnormal rhizogenesis indicates that inhibitor material prevents the microtubule formation. Lateral rhizogenesis or damage of primary root indicates that hormonal balance is destroyed. The difference between the length of the root and stem indicates that plant growing is affected at the primary level. These effects depend on the impact of the compound's mechanism of action and biologic effect, which have extracted an allelochemical effect, as well as the target plant's physical and biochemical tolerance status (Erez, 2009). As a result of the secondary metabolites' or allelopathic compounds' interaction with the target plant, temporary pores may open on the cell membrane or they may cause membrane disintegration. Thus, by increasing cell membrane permeability, they may make them open to exogenic materials (Wink, 2010). Also, these compounds can easily react with proteins and toxic materials, which have a significant role in metabolic and structural events, gene regulation and interaction. As a result of this interaction, protein conformation may easily become active or inactive. Secondary metabolites perform this effect by connecting proteins covalently, especially with their own reactive functional groups (Wink & Latzbruning, 1995). Moreover, allelopathic agents, which contain phenol, may decrease, increase or cap off the plant hormones' physiological activities. This situation inhibits plants' normal physiological development process. In general, phenolic compounds' effect on germination and early seedling development may be activating or inhibiting depending on the compound that is used, concentration and target plant (Reigosa et al. 1999).

PREVIOUS STUDIES ON THE EFFECTS OF COUMARIN ON PLANTS

Coumarin's significant effects such as acting like an antioxidant, an enzyme inhibitor and in repressing toxicants are examined in plant biochemistry and physiology (Yuksel, 2017; Abenavoli et al. 2003; Saleh et al. 2015). Coumarins in plants facilitate or inhibit plant development depending on their types and concentrations. A plant affects call differentiation and auxin metabolism by acting like development promoter (Abenavoli et al. 2003; Demiralay, 2005; Yuce, 2006).

Coumarin's influence on *Vicia faba* L was examined by considering some parameters like germination and growth in the study of Saleh et al. in 2015. To determine coumarin's influence on germination, the *Vicia faba* L seeds were treated with coumarin in different concentrations. It is stated that coumarin influenced the plant more in growth phase, significantly enhanced phytohormone rates as well as primary and secondary metabolites. Results of Saleh et al.'s study indicated that coumarin might influence plant's growth and physiology as an active growth substance and it might have an interaction with phytohormone metabolism.

In Razavi's (2011) study, it is stated that some coumarin derivatives like imperatorin and psoralen may be used for producing eco-friendly pesticide chemicals. Mata et al. (1998) used *Amaranthus hypochondriacus*, which is an imperatorin of a natural coumarin derivative on *Echinochloa crusgalli*, *Lactuca sativa* and *Lycopersicum esculentum*. They examined the effects of coumarin on radicle growth and germination. Based on their findings, they reported that, imperatorin inhibited ATP synthesis and phosphorylation mechanisms, and acted like an allelopathic agent on these plants.

Wu et al. (2016) applied 40 $\mu\text{g mL}^{-1}$ coumarin on Italian rye flower (*Lolium multiflorum* Lam.), common knotgrass (*Polygonum aviculare*), red clover (*Trifolium pratense*), veronica (*Veronica persica*), *Poa pratensis* L., *Chenopodium album* and *Plantago asiatica* plants and found out that coumarin, in these plants, significantly inhibited the seed germination and seedling growth. It is stated that important inhibition effects denoted both seed germination and seedling growth on all coumarin applied test plants in 80 $\mu\text{g mL}^{-1}$. They also stated that coumarin completely hindered Italian rye flower's and red clover plant's seed germination and seedling growth. Results of their study revealed that coumarin was the dominant allelochemical substance of yellow sweet oat and this substance had a powerful inhibition effect on seed germination and seedling growth on many weeds. According to the results of this study, coumarin may be used as a natural herbicide.

Razavi et al. (2010) conducted a study on *Zosima absinthifolia* plant which belongs to the Apiaceae family. This plant is used as food aroma and food product in Iran. In this study, imperatorin, which is one of the plant seeds known as furanocoumarin, 7-preniloksi coumarin, and auraptene were purified. Results of their study revealed that imperatorin displayed a fungi toxic effect against *Sclerotinia sclerotiorum*, which is a common plant pathogen. It is stated that compounds also had phytotoxic effects and they played an allelochemical role.

Findings of Shettel and Balke's (1983) study revealed that coumarin derivative umbelliferon inhibited the growth of *Zea mays* L., *Glycine max* L., *Abutilon theophrasti* Medic., *Amaranthus retroflexus* L., and *Panicum miliaceum* L. plants. In the study of Kupidowska et al. (1994), the effects of coumarin and xanthotoxin substances on *Allium cepa* plant were examined. It is reported that these substances retarded mitosis in *Allium cepa* root tips meristematic cells, decreased oxygen uptake by its meristematic cells, created structural changes in mitochondrial matrix and caused changes in organelles' formation and physiology. The results of third study revealed that coumarin increased succinate dehydrogenase enzyme production more than xanthotoxin, and energy metabolism was affected as a result of the subsequent changes. Similar to the findings of Razavi et al. (2010), they found that coumarin acted like allelochemicals.

In another study, Brooker et al. (2007) examined coumarin's six different derivatives in terms of their antifungal activity against pathogen fungi on various soil plants. They were specifically interested in *Macrophomina phaseolina* and *Pythium* spp., pathogens amongst these fungi. Their results supported previous studies about natural insecticide development with the help of coumarin and its derivatives.

Al-Barwani et al.'s (2004) study found that coumarin derivative furanocoumarins were dominant antifungal compound on *Conium maculatum* plant. Along with these compounds' absence in healthy plant structurally, they increased 103 times more in plants that got stressed compared to the control group. The findings of their study suggested that these compounds

might be considered as stress compounds because they increased as a result of chemical stress.

There were some other studies on coumarin, which examined its insecticidal effects. For example, Olson and Roseland (1991) and Stevewnson et al. (2003) found that coumarin and its derivatives had insecticidal effects. In the light of the findings of these studies, it is stated that working on coumarin may bring a new approach to the development of genetic plants that produce coumarin by using genetical engineering and to the control of insect herbivores.

In another study Ahrabi et al. (2011) investigated the biochemical and physiologic reactions of para-hydroxybenzoic acid and coumarin, which are the secondary metabolites from phenolic compounds that affect plant growth and development on canola. Chlorophyll, carotenoid and anthocyanin ingredients were identified and catalase activities were measured. Moreover, lipid peroxidation was measured with thiobarbituric acid. The results of the study revealed that seedling growth decreased significantly. It is stated that chlorophyll ingredient decreased with the increase in phenolic compounds' concentrations however carotenoids and antioxidants like anthocyanin that had low molecular weight decreased significantly. It is reported that antioxidant enzyme guaiacol peroxidase activity increased along with the increase in phenolic compound concentration but catalase activity did not change significantly. In spite of the increase in the antioxidant capacity of canola seedlings, it is explained that lipid peroxidation increased in the presence of these phenolic compounds. The results revealed that some plants' allelopathic potential was related with its phenolic compounds and allelochemical research may cause development of herbicides that had less negative effect on environment and ecosystem. It is reported that these phenolic acids' presence may decrease canola yield and it is prominent to destroy these weeds for the production of canola in terms of an allelopathic angle.

In their study, Abenavoli et al. (2006) investigated allelochemical coumarin on *Triticum turgidum sperması durum* Desf. plant. Findings of their study revealed that coumarin inhibited the seed germination in high concentrations. More specifically, coumarin blocked the water intake, lessened the electrolyte storage capacity and O₂ consumption during early germination stage and delayed the activation of peroxidases. It also increased superoxide dismutase activity, decreased some enzymes' (APX, CAT) activities and suppressed some molecular chaperons' transcriptions. In another study, Aliotta et al. (1992) investigated coumarin's effects on radish. The results of the study revealed that coumarin was an effective inhibitor and it inhibited the root growth of carboxylic group in the side chain.

Zhou et al. (2013) investigated the effects of coumarin application on the growth of *Medicago Sativa*, net nitrate intake, nitrate (NO₃⁻) and ammonium (NH₄⁺) concentration, the amount of soluble protein and the effects on nitrate reductase, glutamine synthase and glutamate dehydrogenase activities. They found out that coumarin decreased the fresh weight production and root/body development rate at shoots and roots in high concentrations. Net nitrate intake was stimulated significantly at the seedlings that were exposed to coumarin in low concentrations but it diminished with the increase in coumarin amount. Their results also revealed that while low coumarin application increased NO₃⁻ ingredient prominently, it decreased in high coumarin application. NH₄⁺ rate, on the other hand, decreased in low coumarin concentration, but increased in high concentration. It is reported that nitrate reductase activities were suppressed in high coumarin concentrations and glutamine synthase rates decreased at first but then increased. It is also stated that glutamate dehydrogenase activities were precluded at roots in the highest coumarin concentrations. According to these

results, it is stated that coumarin in low concentrations stimulated net nitrate intake and N metabolism at roots but in high concentrations it affected the basic enzymes of nitrogen metabolism in clover.

Based on the results of their study, Li and Gao (2011) stated that a coumarin derivative 4-metilumbelliferon (4-MU) inhibited seed germination by decreasing primary root growth in *Arabidopsis thaliana*. It is also found that 4-MU contributed to the hypocotyl formation and auxin distribution. In another study, Abenavoli et al. (2003) applied coumarin (1,2 benzopyrone) on *Daucus carota* L. Cv. Saint Valery. As a part of their study, they generated plant culture in order to investigate the effects on cell growth and nitrate intake and the use of ammonium and carbohydrates on this plant. While coumarin application caused cell growth inhibition, free amino acids, ammonium rates and glutamine synthetase; glutamate dehydrogenase, glukoz-6-fosfat dehydrogenase and phosphoenolpyruvate carboxylase enzyme activities increased in cells. It is stated that malate dehydrogenase, on the other hand, was inhibited. These effects were interpreted from the point of protein catabolism's stimulation and/or intervention with the protein biosynthesis which was induced by coumarin. Similar to other studies discussed in this review, in this study, it is stated that allelochemical compound coumarin might act as an inhibitor of cell cycle and/or as a senescence-promoting substance.

In another study, Abenavoli et al. (2004) investigated the effects of coumarin on corn seedlings (*Zea mays* L. cv. Cecilia) when the parameters like the length, diameter of different root types and branching density were taken into consideration. The amount of applied coumarin inhibited the root length. It is also found that especially 1 and 0.25 mM coumarin concentration decreased radical, seminal and nodal root lengths, respectively. In the light of the results that they found, it is stated that nodal > seminal > radical plant roots were more sensitive to coumarin.

Another study that investigated the allelochemical effects of coumarin was Lupini et al. (2010). It focused on the effects of coumarin on root elongation speed at three different maize primer root zones, transition zone and two non-growing zones. ATPase activity, pH changes and cell membrane potentials at root zones were evaluated. According to the results of the study, it is stated that coumarin increased root elongation speed at root transition zone thus, it caused an increase in ATPase activity. It is reported that cell membrane permeability changed by causing proton amount change.

In a different study, Al-Wakeel et al. (2013) applied three different concentrations of coumarin and salicylic acid against charcoal rot disease caused by *Macrophomina phaseolina* (Tassi) Goidanich on sunflower (*Helianthus annuus* L.). It is stated that the preparation of sunflower seed with 0.3 mM coumarin or 1.0 mM salicylic acid reduced the degree of disease and provided approximately 50% protection on the length of root lesions at greenhouse conditions and more than 80% decrease. It is reported that both coumarin and salicylic acid applications caused accumulation of soluble sugars and phytoalexins, at the same time they also stimulated β -1,3-glucanase and chitinase activities.

Pergo et al.'s (2008) study focused on nine different plants against *Bidens pilosa* L in terms of phytotoxicity. *Bidens pilosa* L grows in Brazil and it is responsible for yield loss at some products. In their study, while coumarin treatment inhibited *Bidens pilosa* L development, it did not affect the development of surrounding useful plants (*Senna obtusifolia* L., *Euphorbia heterophylla* L. ve *Ipomoea grandifolia* L.). Among the results of the study, it is stated that coumarin acted like a cytostatic agent which retarded germination.

Saleh and Madany's (2015) study investigated the effects of coumarin in increasing endurance against salinity stress of the plant. They covered wheat germs with coumarin (50ppm) and then grew them under different NaCl levels (50, 100, 150 mM) during two weeks. Because of the accumulation of osmolytes like soluble sugars and proline with coumarin pretreatment, it enhanced the growth of wheat germs under salinity compared to the seedlings that coumarin was not applied. Also, coumarin treatment significantly increased K^+/Na^+ rates at plants' seedlings' shoots that were under salinity stress. In addition to this, it is stated that at roots, this rate increased in the plans that have no salinity stress. It is found that phenolic materials and flavonoids accumulated with coumarin treated Phenylalanine ammoniac lyase (PAL). Salt stress significantly stimulated peroxidase (POD) activity at the seedlings that were pretreated with coumarin. Additionally, the effects of coumarin on total antioxidant capacity was obtained only with the highest NaCl doze (150 mM).

Saleh and Kebeish (2017) demonstrated that coumarin and its derivatives had different physiologic effects on tissue and organ levels. In their study, coumarin's effect on redox homeostasis of wheat germs at aleurone layers was investigated. The results revealed that both coumarin and GA3 implementations induced α -amylase production but inhibited superoxide dismutase, catalase and ascorbate peroxidase activities. Antioxidant enzymes' downregulation by coumarin and GA3 caused both H_2O_2 and significant accumulation of malondialdehyde. The results showed that coumarin might ruin redox balance at aleurone layers by inactivating enzymatic antioxidant system. It is stated that, coumarin may show gibberellin-like activity. In another study, Saleh and Abu El-Soud (2015) also found that coumarin had a gibberellin-like effect and it was effective in germination and sapling formation.

In the investigation of new plant killer compounds that cover weeds, Araniti et al. (2015) examined the effects of three synthetic coumarin derivatives on two harmful weeds, *Amaranthus retroflexus* and *Echinochloa crus*' germination and rhizogenesis. All of the coumarin derivatives that they synthesized affected both weed germination and rhizogenesis. Findings of their study revealed that coumarin and its derivatives might have promising herbicide activity potential.

Niro et al. (2016) define coumarins as having allelopathic characteristics. In their study, researchers investigated the effects of different doses of coumarin on a weed (wild oat), crop (wheat) and microbial community in natural soil conditions. Findings of their study reaffirmed that coumarin was a natural herbicide that had a prominent potential in sustainable agriculture. In another study, Grana et al. (2017) evaluated the mechanism of action and phytotoxic potential of scopoletin, which is a natural compound that belongs to the coumarin group. Results of their study demonstrated that scopoletin caused mitochondrial membrane depolarization and rhizogenesis that stimulated cell death. With the analysis conducted, they observed cell and tissue anomalies at roots, such as cell wall deformations, multinucleate cells, abnormal nuclei and tissue disorder.

Lupini et al. (2014) also defined coumarin as an active allelopathic compound that played a key role in plant-plant interaction and communication. The interaction between coumarin and auxin was examined at *Arabidopsis thaliana* (Col-0) on root system's development. It is stated that coumarin strongly affected *Arabidopsis* seedling's primary root extension and root development. It is also found that especially 10^{-4} M coumarin significantly inhibited main root extension by increasing lateral root numbers and root bristle length. Also, coumarin addition increased the negative effects of TIBA and NPA which were the two auxin transport

inhibitors that caused lateral root formation's inhibition. These results revealed that there was a functional interaction between coumarin and auxin in the root development of *A. thaliana*.

Yuksel and Aksoy (2017) examined the cytological effects of Coumarin (2H-1-benzopyran-2-one) on *Lens Culinaris Medic* in terms of cell response, mitotic index, mitotic abnormalities and chromosome aberrations. Germination percentages of *L. culinaris* roots decreased with increasing coumarin concentrations. Cytological observations demonstrated that the mitotic frequency in root meristematic cells decreased and that abnormality frequency also decreased in parallel to the increase in concentrations of coumarin. The results indicated that this active ingredient had the ability to cause a reduction in the seed germination percentage in the number of different phases of mitosis and increased chromosomal aberration of *L. culinaris*.

CONCLUSION

As I have tried to present in this chapter, coumarin and its derivatives have a wide range of applications in different plants for different purposes. Nowadays, the active use of coumarin and its derivatives, which are used as defense elements, in several areas such as agriculture, food, cosmetics and medicine, necessitates the clarification of action mechanisms of coumarin. In order to understand these compound's allelopathic and toxic effects completely, it is essential to carry out cytological, genetic, biochemical and physiological tests together. With the studies that are conducted on plants, it is highly important to understand the defense mechanisms in plant species that are resistant to stress conditions in order to minimize yield loss in terms of nutrition and agricultural economics. For this purpose, most of the studies have focused on the production of plant species that are resistant to stress conditions in recent years. These studies are also offering solutions to prevent nutrition problems that are likely to emerge in the near future.

Chapter 275

AWARENESS OF BRUCELLOSIS: A WORLDWIDE ZONOSIS

Mustafa Sencer Karagul*

Kartepe Vocational School of Equine Science,
Kocaeli University, Kocaeli, Turkey

ABSTRACT

Brucellosis, which is one of the most common zoonotic diseases, causes abortion, infertility and reduced milk production in animals. Brucellosis in humans, on the other hand, is defined as an acute or sub-acute febrile illness including an intermittent or remittent fever. Because of brucellosis, many countries run the risk of suffering from economic and health problems like losing husbandry and infection risks. *Brucella*, which dates back to the 5th plague of Egypt around 1600 BC in history and which was named after the research of Sir David Bruce, is an important disease and *brucella* genus has 11 species. The aim of this chapter is to define this disease and its species and biovars, to explain its historical background, and to reveal the ways it affects animals and humans.

Keywords: biovar, *Brucella melitensis*, brucellosis, Malta fever, zoonosis

INTRODUCTION

Brucellosis is one of the most common zoonotic diseases caused by *Brucella (B.)* spp., which causes important health and economic problems (Godfroid et al., 2005; Songer & Post, 2012; Yumuk & O'Callaghan 2012). This disease, which has subacute or chronic forms, affects many different animal species (Corbel, 2006). It causes both economic and health problems through the loss of husbandry and it brings about risks due to the infections appearing via dairy products (Pappas et al., 2006a; Seleem et al., 2010). The distribution of host includes humans, wild and domestic animals such as sheep, goat, cattle, camel, pig, boar,

* Corresponding Author's Email: msencerk@hotmail.com.

rabbit, dog, marine mammals, fox, and baboon (Corbel, 2006; Godfroid et al., 2005; OIE, 2016; Songer & Post, 2012). It is defined as a chronic contagious disease causing necrotic inflammatory infections and complications such as abortion, infertility, arthritis, orchitis and mastitis in susceptible hosts (Alton et al., 1988; Aydin, 1997). Moreover, World Health Organization (WHO) laboratory biosecurity manual describes *Brucella* organisms as belonging to risk group 3 microorganisms (OIE, 2009a; OIE, 2012; WHO, 2004).

As *Brucella* species can be transmitted via aerosol way, it is classified as a potential bioterror agent as well. It is also stated that there are no vaccines for human beings (Godfroid et al., 2005; Songer & Post, 2012). Because of its significance as a potential agent of bioterrorism, the pathogen is on the category B biodefense research list of the Centers for Disease Control and Prevention (CDC) and the National Institute of Allergy and Infectious Diseases (NIAID). The non-stratified lists of potential biological weapons of other organizations, such as the WHO, the North Atlantic Treaty Organization (NATO), and the Biological and Toxin Weapons Convention (BTWC) also include brucellosis (Pappas et al., 2006a). When it is used as a weapon for agroterrorism, it might ruin the economy (DelVecchio & Mujer, 2013).

Brucellosis is known as ‘undulant fever’, “Mediterranean fever” or “Malta fever” (Corbel, 2006; Godfroid et al., 2011; Matthew & Leland, 2004) and it is transmitted through infected animals or their products (Corbel, 2006). However, Mediterranean fever, which is synonymous with brucellosis, should not be confused with familial Mediterranean fever. (Matthew & Leland, 2004). Brucellosis, especially caused by *Brucella melitensis*, remains one of the most common zoonotic diseases worldwide with more than 500,000 human cases reported annually (Bosilkovski et al., 2009; Pappas et al., 2006b; Seleem et al., 2010).

Brucellosis in cattle is usually caused by biovars of *Brucella abortus*. In some countries, especially in southern Europe and western Asia, where cattle are kept together with sheep or goats, *B. melitensis* might cause this infection (OIE, 2012). Brucellosis in cattle is known as Bang’s disease and epizootic abortion and contagious abortion are the terms that also used in veterinary medicine. (Matthew & Leland, 2004). Brucellosis in sheep and goats (excluding *Brucella ovis* infection) is primarily caused by one of the three biovars of *B. melitensis*. (OIE, 2009a). *Brucella ovis* causes a disease unique to sheep and it is one of the most common causes of epididymitis in rams and a rare cause of infertility and abortion in ewes and neonatal mortality in lambs (OIE, 2015a). Sporadic infections caused by *B. abortus* or *B. suis*, which are rare cases, have been observed in sheep and goats. On the other hand, it is possible to observe *Brucella melitensis* infection in domestic and wild susceptible species when these species are kept together with sheep and goats in enzootic areas (OIE, 2009a). Out of 5 biovars of *B. suis*, biovars 1, 2 and 3 are responsible for the infection in pigs (OIE, 2009b). Canine brucellosis, which is a zoonotic disease and caused by *Brucella canis*, is an important cause of reproductive failure, particularly in kennels (CFSPH, 2012).

THE HISTORY OF THE DISEASE

It is possible to trace the roots of this disease in the 5th plague of Egypt around 1600 BC. When ancient Egyptian bones dating to around 750 BC were examined, some evidence of sacroiliitis and other osteoarticular lesions, common complications of brucellosis was found

out (Pappas, 2006a; Seleem et al., 2010). In addition, a researcher named L. Capasso found the bone lesions which were typical of brucellosis in the skeletal remains of people who died during the first volcanic eruption of Mount Vesuvius. He also analyzed a buried carbonized cheese through electron microscopy and his analysis revealed that there were coco-like forms which were morphologically consistent with *Brucella* spp. (D'anastasio et al., 2011; Godfroid et al., 2005; Seleem et al., 2008). Since people domesticated animals, brucellosis has affected human populations. There is evidence that Hippocrates might have mentioned it in his book titled 'On Epidemics' and it was a common disease in the ancient world (Matthew & Leland, 2004).

The disease, which is known as brucellosis, was first found out in Malta in 1850s. It was the British medical officers serving on the island who spotted the disease after the Crimean War (Wyatt, 2013). In 1859, Marston made one of the earliest descriptions of the disease in 1859 except for the biblical references (Nicoletti, 2002). He also described typhoid fever and differentiated it from 'Undulant fever', what is known as brucellosis (Nicoletti, 2002; Wyatt, 2013). The research of Sir David Bruce with the military and civilian population in Malta started the modern understanding with the help of the identification of a micrococcus from a patient who died of undulant fever in 1887 and it was named '*Micrococcus melitensis*' (Godfroid et al., 2005; Matthew & Leland, 2004; Poester et al. 2013; Wyatt, 2013). In 1905, again in Malta, Themistocles Zammit isolated it from goat's milk accidentally and thanks to this, he was able to illustrate the zoonotic nature of the disease. Before that, it was considered to be a vector-borne disease (Nicoletti, 2002; Seleem et al., 2010). This bacterium was renamed '*Brucella melitensis*' in Sir David Bruce's honor by Meyer and Shaw in 1920 (Poester et al., 2013).

Afterwards, L.F. Bernhard Bang, who was a Danish vet, mentioned an organism that he named *Bacillus abortus* which caused contagious abort cases in cattle, which was later found to be associated with Bruce's organism (Matthew & Leland, 2004; Nicoletti, 2002; Seleem et al., 2010). The name of the disease was changed from 'Bovine infectious abortion to Bang's disease in 1930 (Nicoletti, 2002). An American scientist, Alice Evans, who carried out important work on pathogenic bacteria in dairy products identified once again the relationship between Bang's disease and Malta Fever and she renamed the genus *Brucella* to honour David Bruce (Parascandola, 1998; Seleem et al., 2010).

Brucellosis in pigs caused by *Brucella suis* was first reported in 1909 by Huntyra in Hungary (Ozcanarlan, 2011). Soon after that, in 1914, Jacob Traum isolated it from aborted swine fetuses in Indiana, USA. (Nicoletti, 2002; Ozcanarlan, 2011; Poester et al., 2013). *B. ovis*, which causes epididymitis in rams, was first isolated in New Zealand by McFarland and his colleagues. In 1953, Buddle ve Boyes stated that this agent was a variant of *B. melitensis*. This agent was named as *B. ovis* in 1956. (Nicoletti, 2002; Ozcanarlan, 2011; Poester et al., 2013). *B. neotomae* was first isolated in Utah, USA in 1957 from the wood rat *Neotoma lepida* by Stoenner ve Lackman. This organism was defined as a new *Brucella* species on the basis of its behavior on differential dye media, CO₂ requirements, and H₂S production (Cameron & Meyer, 1958). *B. canis* was discovered in beagle dogs in the USA in 1966 and named as a distinct species by Carmichael in 1968 (Thimm, 1982). It is the germ of contagious abortion of kennel dogs and stray dogs as well. In 1994, British researchers isolated an unknown *Brucella* organism from stranded harbor seals (*Phoca vitulina*), harbor porpoises (*Phocoena phocoena*) and common dolphins (*Delphinus delphis*) on the coast of Scotland, and American researchers isolated it from an aborted foetus of a captive bottlenose

dolphin (*Tursiops truncatus*) in California (Godfroid et al., 2005). The distinguishing metabolic profiles, dye and phage sensitivities of these isolates were found to be the same and then, they were labelled as *B. maris*. (Ozcanarslan, 2011). Later on, *B. maris* was categorized as *B. ceti*, which affects porpoises and dolphins, and *B. pinnipedialis*, which affects mainly seals. (Pappas, 2010). Previously, brucellosis was not recognized, not even suspected in marine mammals; however, as marine mammal *brucella* strains have been isolated, the ecologic range of the genus and its scope as a zoonosis have been extended. (Godfroid et al., 2005).

In Turkey, the first brucellosis case was identified by Husamettin Kural and Mahmut Sabit Akalin in 1915 in a soldier who was being treated in Istanbul Kuleli Military Hospital. The first isolation in cattle was made in 1931 by Berke and in sheep by Koylubag and Aktan in 1944 in Bandirma Merinos Farm (Aydin, 1997; Celebi, 2003; Cevik, 2001; Golem, 1949; Iyisan et al., 2000). Golem revealed the existence of brucellosis in humans and animals through serological methods (Aydin, 1997; Iyisan et al., 2000). In Turkey, the first documented case of brucellosis, which was confirmed by a laboratory, was in 1915 despite the fact that it is believed that Florence Nightingale got this disease during the Crimean War in Turkey (Young, 1995; Yumuk & O'Callaghan, 2012).

BRUCELLA SPECIES AND BIOVARS

The microorganisms belonging to *Brucella* genus are not mobile; they are sporeless and gram-negative and in the form of small coccobacilli (Aydin, 1997; OIE, 2012; Thimm, 1982). They are bacteria-like rods and they are 0.5 - 1.5µ in length and 0.5 - 0.7 µ in breadth (Alton et al., 1988; Corbel & Banai, 2005; OIE, 2012; Thimm, 1982). They grow in the presence of oxygen at an optimal temperature of 37°C (within the range of 20 - 40°C) and an optimal pH of 6.6-7.4.(Corbel & Brinley Morgan, 1982; Thimm, 1982; WHO, 1986). Another characteristic of *Brucella* spp. is that even though they are defined as immobile, they possess all the genes required to form a functional flagellum except the chemotactic system (Seleem et al., 2008; 2010).

In general, the morphology of *Brucella* strains is constant and pleomorphic forms are rare, except in old cultures growing under adverse conditions. Just because they are small and coccoid, they can be confused with cocci (Alton et al., 1988; Corbel & Banai, 2005). When serum or blood is added to the media, they foster the growth of *Brucella* spp. and a 5-10% CO₂ atmosphere is a necessity for some strains of *B. abortus* (biovars 1 - 4 and 9) (Aydin, 1997; Perez-Sancho et al., 2015). They produce oxidase, catalase, nitrate reductase, urease; they do not produce indole; they are not hemolytic, do not melt gelatine, and also Methyl Red (MR) and Voges-Proskauer (VP) test results are negative. Most of them, except for *B. ovis*, use glucose as the source of energy (Songer & Post, 2012). When *Brucella* microorganisms are listed as taxonomies, the *Brucella* genus is defined as belonging to the family *Brucellaceae* within the order Rhizobiales of the class *Alphaproteobacteria* (Godfroid et al., 2011; Songer & Post, 2012). They belong to the alpha-2 subcategory of the *Proteobacteria*, together with *Ochrobactrum*, *Rhizobium*, *Rhodobacter*, *Agrobacterium*, *Bartonella*, and *Rickettsia* (Seleem et al., 2010). Molecular studies have shown that a non-pathogenic soil organism was possibly the predecessor of *Brucella* as true pathogens (Bardenstein et al.,

2010). *Brucella* bacteria are genetically related to some plant pathogens and symbionts of the genera *Agrobacterium* and *Rhizobium*, in addition to animal pathogens (*Bartonella*) and opportunistic or soil bacteria (*Ochrobactrum*) (OIE, 2012). The closest phylogenetic neighbor of the genus *Brucella* is the genus *Ochrobactrum anthropic* as a saprophyte, which rarely infects animals (Godfroid et al., 2011). It is also claimed that *Brucella* organism is a species of *Ochrobactrum* (Pappas, 2010).

After *Brucella* bacteria have been observed in different animal species and different environments, *Brucella* genus is claimed to include 11 *Brucella* species (OIE, 2016). *B. abortus*, *B. melitensis*, *B. suis*, *B. ovis*, *B. neotomae* ve *B. canis* are considered to be classical species. This classification is based on pathogenic differences and host preferences (Altöparlak, 2003; ICSP, 2014; Vicente et al., 2014), specific phages and lysis sensitivity, their oxidation ways in various carbohydrate and amino acid substrates (Gorvela & Moreno, 2002; Yumuk & O'Callaghan, 2012) and their other phenotypic characters. Out of 6 classical species, 5 of them lead to infection on one or more animal hosts and cause clinical symptoms. 4 of them; namely, *B. melitensis*, *B. suis*, *B. abortus* and *B. canis* (listed according to their pathogenicity) cause infection on humans (Corbel, 2006; Matthew & Leland, 2004; Seleem et al., 2010).

Biotyping is considered as a perfect way of finding and clarifying epidemiological data (Thimm, 1982). It is possible to divide *B. melitensis*, *B. abortus* ve *B. suis* into different biotypes based on the analysis of their requirements of CO₂, their production of H₂S, their growth on cultural media which contain dyestuffs, and their reaction to monospecific antisera (Cloeckaert et al., 2002; OIE, 2012; Thimm, 1982). *B. pinipedialis* and *B. ceti*, which are hosted by marine mammals, are different from other *Brucella* species phenotypically with regards to their metabolic activity (Jahans et al., 1997; Seleem et al., 2010). The types which have recently been recognized as related to marine animals can also cause human disease (Corbel, 2006; Seleem et al., 2010). Another new species that has been recognized in central Europe in common voles and red foxes is *B. microti*. It is also considered to be a persistent soil contaminant. The agent has not been linked with human disease but if it has an anthroponozoonotic risk, a particular target group would be hunters (Pappas, 2010). Hosts preferred mainly by *Brucella* species and their pathogenicity levels are shown in Table 1 (Godfroid et al., 2011; OIE, 2016).

Two new strains, in addition to the already recognized *Brucella* strains, have each been isolated from a single human case (Pappas, 2010). The first one (BO1T) has been labelled as *Brucella inopinata*. The name '*inopinata*' comes from Latin, which means '*unexpected*'. It was isolated from the breast implant wound fluid and blood of a female patient, who was 71 years old and who had the clinical symptoms of brucellosis. (Scholz et al., 2010). The second strain (BO2 strain) was isolated from the lung biopsy of a 52-year-old patient in Australia, who had a history of chronic destructive pneumonia. The analysis of the isolate has shown similar characteristics with *B. inopinata* (Tiller et al., 2010).

Strains are either smooth or rough, which express smooth lipopolysaccharide (S-LPS) and contain O-chain, or rough lipopolysaccharide (R-LPS), and which lack O-chain, as major surface antigen, respectively (Cloeckaert et al., 2002). S-LPS is the most significant antigenic form in the infections caused by smooth *Brucella* organisms and it serologically belongs to immunodominant epitopes, O-polysaccharide (O-PS) section. LPS layer of rough mutant *Brucella* bacteria lacks O-PS and they just carry coreolysaccharide-Lipid A part (Cloeckaert et al., 2002; Godfroid et al., 2011). LPS is a very important form for the structural and

functional integrity of the outer membrane of the gram-negative bacteria. When compared to the classical enterobacterial LPS, the ones belonging to *Brucella* are a lot less active and less toxic than *Escherichia coli* (Seleem et al., 2008).

Table 1. *Brucella* species, preferred hosts and pathogenicity for humans

Species	Biotype	Preferred hosts	Pathogenicity for humans
<i>B. melitensis</i>	1 - 3	Goat, sheep	High
<i>B. abortus</i>	1 - 6,9	cattle	High
<i>B. suis</i>	1 - 3	pig	High
	2	wild boar, hare	None ^a
	4	Reindeer, caribou	High
	5	Rodents	High
<i>B. neotomae</i>	-	Desert wood rat (<i>Neotomalepida</i> Thomas)	High
<i>B. ovis</i>	-	Ram	None
<i>B. canis</i>	-	Dog	Moderate
<i>B. ceti</i>	-	Ceteceans	Unknown ^b
<i>B. pinnipedialis</i>	-	Pinnipeds	Unknown ^b
<i>B. microti</i>	-	Soil, vole, fox	Unknown
<i>B. inopinata</i>	-	Unknown	High
<i>B. papionis</i>	-	Unknown	Unknown

a. One case of *B. suis* biovar 2 infection in an immuno-compromised hunter has been described in France.

b. One human laboratory contamination has been described in the UK. Two naturally acquired cases have been described, although the source of infection could not be traced back to marine mammals.

B. ovis ve *B. canis* are two *Brucella* species which are currently known as being naturally in the rough phase. *B. ovis* has similarities with other *Brucella* species in that they are alike in terms of their morphology, their staining properties and their cultural characteristics; however, the reactions of *B. ovis* to the oxidase and urease tests are negative. *B. ovis* colonies are not haemolytic. They are circular and convex and they have edges, which are unbroken. Moreover, they are always rough when they are examined by oblique illumination and test positive in the acriflavine test (Alton et al., 1988; OIE, 2015a). *B. ovis* requires an incubating atmosphere which has 5 - 10% CO₂ for growth. In addition, it is lysed by Rough/Canis phage (Alton et al., 1988; OIE, 2015a).

Finally, a new species, *B. papionis*, has been added to the *Brucella* genus (OIE, 2016). The phenotypic and genotypic analysis of 2 isolates obtained from stillborn baboon offsprings has shown that these isolates belong to *Brucella* genus. Detailed analysis of the strains has illustrated that these two strains have a new lineage within the genus *Brucella* (Whatmore et al., 2014). All these developments have brought to mind the question whether *Brucella* agents started to appear in the woods as well as the oceans (Pappas, 2010).

The studies of DNA-DNA hybridization have illustrated that there is more than 90% homology between recognized *Brucella* species (Cloeckaert et al., 2002). For this reason, in 1985, combining the 6 species into one single species, which is *B. melitensis*, and recognizing the other species as biovars, was suggested (for example, *B. melitensis* biovar abortus 1) (Cloeckaert et al., 2002; Godfroid et al., 2011; Pappas, 2010; Verger et al., 1985). However, in 2003, the subcommittee on *Brucella* taxonomy decided to go back to the previous version of the taxonomic treatment of *Brucella* genus and approved once again the six classical *Brucella* nomenspecies with their corresponding biovars (Pappas, 2010).

It is known that *Brucella* spp. can persist in milk for a period of time (even when the milk turns sour) and they continue growing in soft fresh cheese. They may also persist in ice-cream for weeks and in butter for months. Thus, it is suggested that these products should be made from pasteurized milk. What is more, *Brucella* spp. can also persist in soil and tap water (Godfroid et al., 2005). In moist soil and in dung, *Brucella* spp. can persist for 70 - 80 days. It is also stated that *B. melitensis* can persist for 15 - 40 days in dust but it depends on the humidity (Doganay & Aygen, 2003). Another point is that hard cheese made through lactic and propionic fermentation is less risky because *Brucella* agents die fast when acidity decreases below pH 4, and they die very fast when it drops below pH 3.5. It has also been pointed out that yoghurt and sour milk are less dangerous. For this reason, soft cheese made from fresh milk can include a lot of *Brucella* organisms and that is why, the products prepared from untreated milk should be avoided (Corbel, 2006). The increase of sodium chloride (NaCl) in dairy products can inhibit *Brucella* spp. (Rowe, 2014).

BRUCELLOSIS IN ANIMALS

It is stated that ingestion of bacteria coming from diseased animals or contaminated feedstuffs lead to most infections. Respiratory exposure and contamination of abraded skin and mucosal surfaces are also the other sources of the infection (Corbel, 2006). On the other hand, *Brucella melitensis*, *B. abortus* and *B. suis* might also be transmitted between animals vertically (Aparicio, 2013). The nasal and oral mucosae, where the organisms are flown into the regional lymph nodes from are the most important points of entry for bacteria. A bacteraemia might be formed from these focal points and the organisms might be situated in other lymphoid tissues such as the spleen and the iliac, mesenteric and supramammary lymph nodes, in which they may bring about a granulomatous reaction. Another bacteraemia leads to a general infection which influences some other organs such as the pregnant uterus, the udder, and their lymph nodes. Uterine lesions are mainly situated in the placentomes. Aborted fetuses and fetal membranes include a high amount of bacteria; thus, they lead to the contamination of the environment, which creates a high risk of infection of sensitive hosts (Poester et al., 2013).

Many factors such as vaccination, age, sex and herd size and density determine whether the disease is severe or not. Abortions stemming from brucellosis are more common in animals which are not vaccinated and there are more organisms shed (Corbel, 2006). More than 85% of *Brucella* might be found in the cotyledons, placental membranes, and amniotic liquid, which might reach up to 1×10^{10} colony-forming units (CFU)/ml in allantoic fluid and 1×10^{13} CFU/g of tissue in the cotyledons in ruminants, which are pregnant (Poester et al., 2013; Yumuk & O'Callaghan, 2012)

The excretion of the organisms in uterine discharges and in milk are considered as the main characteristics of the disease (OIE 2009a; OIE, 2012). Despite the fact that infected animals may abort only once, they remain carriers till the end of their lives. In the mean time, they expel many organisms in their milk and in the following parturitions, which are apparently normal (Yumuk & O'Callaghan, 2012). All infected goats do not abort; however, they can all shed *Brucella* into the environment. Under normal conditions, the main way of infection is not venereal transmission but artificial insemination with contaminated semen

might lead to infection (Poester et al., 2013). When it was found out that healthy goat can carry the disease, it was considered to be one of the most important discoveries carried out in the field of epidemiology (Seleem et al., 2010).

It was pointed out that consumption of feed which was contaminated by birth and/or abortion products and uterine discharges are the main ways of the transmission of the disease in pigs. Pigs can eat fetuses which are aborted and also placental membranes. Transmission of brucellosis during copulation is very common and this process is influential on artificial insemination. *Brucellae* may be excreted in the semen by the boar even though there is nothing abnormal in their sexual organs and it does not interfere with their sexual activity (OIE 2009b; Poester et al., 2013). Infected boar can shed 10^4 - 10^5 CFU/ml of semen, which makes venereal transmission an important way of infection (Perez-Sancho et al., 2015).

All the information regarding animal brucellosis is present on the website of the Office International des Epizooties (OIE) (<http://www.oie.int>) and it can be accessed via the HandiStatus tool (i.e., Help with World Animal Disease Status, version 2). The information of this website is updated regularly depending upon emergency and based on the monthly and annual reports which are sent to OIE by the veterinary administrations of the countries and other official sources (Godfroid et al., 2005). Production systems, agro-ecological zones, husbandry practices, contact with wildlife, and management factors are the main factors, which affect the prevalence of Brucellosis (Godfroid et al., 2011).

Among the pre-defined 6 classical *Brucella* species, except for *B. canis*, *B. ovis* and *B. neotomae*, all these species of *Brucella* form polycyclic chain of infection and they might be transmitted to other animal species and to man when the necessary ecological-epizootic conditions are suitable (Thimm, 1982). In spite of the successful results obtained in most of the industrialized countries, in which bovine brucellosis is no longer a big problem, small ruminant brucellosis is still an important issue (Godfroid et al., 2005). It is widely known that in the Mediterranean region, *B. melitensis* is endemic but it is a widespread worldwide disease. North America including Australia, New Zealand, South-East Asia, Northern and Central Europe (except for Mexico) are thought to be free from the agent (OIE, 2009a). In some Mediterranean countries such as Israel, Kuwait, Saudi Arabia, and Egypt, *B. melitensis* infection in cattle is particularly important and they exemplify *Brucella* agents' potential of causing infection in other hosts as well as its main hosts (Corbel, 1997; Perez-Sancho et al., 2015).

In addition to cattle and small ruminants, it was also reported that brucellosis was identified in both one-humped (*Camelus dromedarius*) and two-humped (*C. bactrianus*) camels as well as South American camelids, llama (*Lama glama*), alpaca (*L. pacos*), guanaco (*L. guinicoe*), and vicuna (*Vicugna vicugna*) (OIE, 2012; WHO, 1986). According to Saleem et al. (2010), when camels are pastured together with infected sheep and goats, they can be infected by *B. abortus* and *B. melitensis*. Although it has been belittled in the Middle East, milk coming from infected camels is one of the most important sources of infection. In some countries, camel brucellosis stemming from *B. melitensis* and *B. abortus* infections is a major source of human infections (Godfroid et al., 2005).

Infected ewes might shed *B. ovis* through their vaginal discharges and their milk. In accordance with this, the transmission from ewe to lamb and the transmission from ewe to ram might be considered as the main source of infection. For this reason, it is important for researchers to consider ewes in accordance with the infection's epidemiology, which is necessary for the effective eradication of *B. ovis* infection. It has also been reported that

infected rams might shed *B. ovis* in their semen for years (OIE, 2015a). The domestic goat, mouflon (*Ovis musimon*), white-tailed deer (*Odocoileus virginianus*) and red deer (*Cervus elaphus*) are also open to infection despite the fact that the most important host species for *B. ovis* is sheep. As stated by (Poester et al., 2013), *B. ovis* is very frequently observed in countries in which sheep raising is common, and which have flock prevalence ranging from 9.1% to 46.7%. *B. ovis* has been observed in the countries of America and Europe and also, in New Zealand and South Africa and it is probable that this disease also occurs in other countries where sheep-raising is common (OIE, 2015a). The prevalence of Brucellosis in pigs is generally low except for such countries as South America and South-East Asia (OIE, 2009b).

B. melitensis bv-2 has recently been reported in catfish in Egypt, which revealed that fish might also be a new source of infection (Yumuk & O'Callaghan, 2012). This fish, namely, *Clarias gariepinus*, is found in the freshwater of the Nile. It has been predicted that this fish has been infected through the meat waste of infected animals which was illegally thrown into the water. Since this fish is edible by humans, it might be a new source of entry of the pathogen to the human food chain. It has been stated that *Brucella* has started to appear in rivers after its existence in oceans and the jungle (Pappas, 2010).

Each *Brucella* type has its peculiar epidemiologic features and as new types appear, the interaction between *Brucella* genus with animals and humans has become complicated. As stated by Corbel (1997) and Godfroid et al., (2005), new *Brucella* strains and types adapt to the social and agricultural practices which are continuously changing. In order to improve the quality of studies, it is necessary to train researchers in terms of formal epidemiology and statistics. If a more integrated approach to disease surveillance, which includes human health and veterinary services is used, it could be easier to understand the dynamics of the disease within the scope of animal-human relationship and resources could be used more cost-effectively (Dean et al., 2012).

HUMAN BRUCELLOSIS

Major risks of brucellosis include contaminated food and the contact with the disease due to people's occupations. In addition, consumption of unpasteurized milk coming from cows, small ruminants or camels and also some other milk products such as cheese, sour milk are the main ways of infection. Similarly, if the meat of animals infected with brucellosis is consumed without being sufficiently cooked, it might be another source of infection (Godfroid et al., 2005; Godfroid et al., 2013; Yumuk & O'Callaghan, 2012). However, meat products are rarely the major sources of infection as they are generally cooked and in muscle tissue, the amount of bacteria is low (Doganay & Aygen, 2003; Matthew & Leland 2004). Infection may be due to the bacteria from infected animals that enter into the body via skin lesions or mucous membranes or when contaminated dust or aerosols are inhaled (Doganay & Aygen, 2003; Godfroid et al., 2005).

Even though *Brucella* is thought to be very infectious when it causes infection through the respiratory route, inhalation is not one of the primary means of infection. However, some occupations such as vets, people working in laboratories or abattoirs are the main risk groups. *Brucella* spp. are believed to be the most common pathogens acquired in laboratories and

they are responsible for up to 2% of all infections coming from laboratories (Seleem et al., 2010). It is stated that infection might occur during the handling of animals, which are infected particularly when these animals are around the time of parturition (Yumuk & O'Callaghan, 2012). The occupation of vets is risky both through the infected animals and their products and through the needlestick injuries when they are inoculating animals with live *Brucella* vaccines (Madkour, 2001; Matthew & Leland, 2004).

It is important to consider evaluating the fever in travelers coming from abroad, particularly the ones who are coming from endemic areas and the ones that report that they were exposed to unpasteurized milk products due to their occupation or diets (Matthew & Leland, 2004; Ragan, 2002). In some countries, the prevalence of human brucellosis coming from dairy products is seasonal and it reaches the highest numbers usually after kidding and lambing (Seleem et al., 2010). *Brucella* in humans is related to many different factors such as geographical factors, husbandary practices, techniques of food preparation, etc. It is also stated that infection can affect all human beings regardless of their age and sex (Bosilkovski, 2015).

When the epidemiology of the disease is considered, humans are believed to be an 'epidemiological cul de sac' of the infection (Thimm, 1982). The transmission of the disease from human to human is rare; therefore, it is not significant in the epidemiology of the disease (Perez-Sancho et al., 2015). Brucellosis in human is not regarded as a contagious one (Godfroid et al., 2005). It is stated that there are very few reported cases occurring through blood transfusion, bone marrow transplant, transplacental way, breastfeeding, sexual intercourse, congenital way and laboratory infection (Godfroid et al., 2005; Godfroid et al., 2013; Poulou et al., 2006; Wang et al., 2015).

In many different geographical regions, which are traditionally regarded as endemic such as France, Israel, and Latin America, the disease is under control. However, human brucellosis now has new foci, especially in central Asia and in certain countries of the near east such as Syria, it is getting worse (Pappas et al., 2006b). In a study published in the year 2006, which outlined the global epidemiology of the disease, it is seen that Central Asia and the Middle East are the main regions of the disease. For this reason, the global map of the disease is the same in 2010 despite the new hot spots added, it even exists in regions in which the infection is least expected (Pappas, 2010). It has been pointed out that in western Europe, where the existing surveillance systems are sufficient, it is not possible for human brucellosis to re-emerge. There are also some eradication campaigns in southern European member countries which will make the spread of the disease inside the EU impossible. (Pappas et al., 2006b). Brucellosis, which is especially caused by *B. melitensis*, is still the most common zoonotic disease worldwide (Pappas et al., 2006a). In addition, when 76 diseases and syndromes observed in animals are reviewed, brucellosis is among the top 10 of the list, which affect poor people (Dean et al., 2012).

The real incidence of human brucellosis worldwide is not known (Corbel, 1997; Doganay & Aygen, 2003). According to the numbers provided by World Health Organization (WHO), there are 500,000 reported Brucellosis cases annually worldwide (Doganay & Aygen, 2003; Perez-Sancho et al., 2015). However, it is estimated that unreported cases, which are happening because of unspecific clinical symptoms, are thought to be ten times higher (Godfroid et al., 2013) or 26 times higher (Bosilkovski et al., 2009). The incidence of the disease, which is reported in endemic areas changes from < 0.01 to > 200 per 100,000 population. The reported low value of incidence in brucellosis-endemic areas which are

known might be because of the lack of surveillance and reporting (Corbel, 1997). Geographic areas, which are regarded as having high level of the prevalence of brucellosis include the Middle East, the Mediterranean Basin (Portugal, Spain, Italy, Greece, Turkey, Near East, North Africa), South and Central America, South-Eastern Europe, Asia, Africa, and the Caribbean (Godfroid et al., 2005; Pappas et al., 2006b; Perez-Sancho et al., 2015).

Despite the fact that there are few reported cases of human-to-human brucellosis cases, human infection mainly stems from domestic and wild animal reservoirs (Godfroid et al., 2011; Godfroid et al., 2013; Thimm, 1982). As human-to-human transmission is rare, infected people do not constitute a threat to the ones around them. Thus, if the disease is eradicated from the animal reservoirs, it will also lower the incidence of human brucellosis (Perez-Sancho et al., 2015; Seleem et al., 2010). In order to overcome the problem of human brucellosis, it is necessary to control and eradicate animal brucellosis (Perez-Sancho et al., 2015).

ABSTRACT

The effects of Arrivo 25 EC (250g/l, Cypermethrin), a pyrethroid insecticide, were investigated on *Hyacinthus orientalis* grown in greenhouse. The insecticide was applied to *H. orientalis* at recommended dosage and double the recommended dosage by manufacturing company. Mitosis was examined in root tip cells and meiosis was examined in anthers. It was observed that the insecticide used in trial applications caused abnormalities in mitosis and pollen meiosis in parallel with the increase in dosage. It is obvious that this condition will have a negative effect on pollen fertility.

Keywords: cypermethrin, *Hyacinthus orientalis*, meiosis, mitosis, mutagenic

INTRODUCTION

Pesticide applications in agricultural and ornamental plants have harmful effects on their cytological mechanisms. Cypermethrin is a synthetic pyrethroid insecticide used to control many pests, including moth pests of cotton, fruit and vegetable crops (Meister, 1992). It is also used for crack, crevice and spot treatment for control of insect pests in stores,

* Corresponding Author's Email: odalgic@yahoo.com.

warehouses, industrial buildings, houses, apartment buildings, greenhouses, laboratories and on ships, railcars, buses, trucks and aircraft. It may also be used in non-food areas in schools, nursing homes, hospitals, restaurants, hotels, and in food processing plants and as a barrier treatment insect repellent for horses (USEPA, 1989). Cypermethrin is a moderately toxic material by dermal absorption or ingestion (Meister, 1992; OHS, 1993). It may cause irritation to skin and eyes. Symptoms of dermal exposure include numbness, tingling, itching, burning sensation, loss of bladder control, incoordination, seizures and possible death. Pyrethroids may adversely affect the central nervous system (OHS, 1993). Cypermethrin is extremely toxic to fish and aquatic invertebrates. The 96-hour LC₅₀ for cypermethrin in rainbow trout is 0.82 ppb, and in bluegill sunfish is 1.78 ppb. Its acute LC₅₀ for *Daphnia magna*, a small freshwater crustacean, is 0.2 ppb. The bioconcentration factor for cypermethrin in rainbow trout was 1200 times in a flow through study (USEPA, 1989). If exposed to cypermethrin during pregnancy, rats give birth to offspring with developmental delays. In male rats exposed to cypermethrin, the proportion of abnormal sperm increases. It also causes genetic damage: chromosomal abnormalities increased in bone marrow and spleen cells when mice were exposed to cypermethrin (Amer et al., 1993). One study showed that cypermethrin inhibited gap junctional intercellular communication, which plays an important role in cell growth and is inhibited by carcinogenic agents (Tateno et al., 1993). Studies have shown that residue from cypermethrin can last for 84 days in the air, on walls, floor and furniture (Wright et al., 1993). Cypermethrin is an environment pollutant and, due to its use, toxicity and persistence, it may cause significant damage to non-target organisms and various ecosystems. This necessitates the development of an effective tool to eliminate or obstruct the concentration of this pesticide (Gangola et al., 2018). Insecticides affect the plants by causing harm to their metabolism, photosynthesis, development and yield. To give an example, malathion formation and carbaryl formulations obstruct the photosynthesis of field grown soybean or the four formulation insecticides, namely flucythrinate, chlordimeform, carbaryl and malathion, lessen the stomatal conductance and lint yield.

The effects of insecticides on growth, fruiting patterns, and yield of Acala-SJ-2 cotton were observed in Wen, et al. (2017). In another study, Sheo Mohan Prasad et al. (2015) found that the decrease in photosynthetic rate caused decreased growth of *A. pinnata* at higher concentrations of both chlorpyrifos and cypermethrin.

Pollen germination was reduced by *in vitro* fungicide applications and degeneration in pollen tubes occurred (Pavlik & Jandurova 2000). Tort et al. (2005) observed that pyrimethanil fungicide caused changes in the structure of tomato pollens. Moreover, it was reported that fungicides resulted various chromosomal abnormalities, such as Deltan applications (0.3%) gave rise to chromatid and subchromatid breaking in red pepper (Prakash & Prathapasanen, 1988). Thiodan, Folithion, Lebaycid and Kitazin caused fragmentation, lagging chromosomes, bridges, tripolar and tetrapolar spindle in barley (Grover & Tyagi, 1980). Therefore, it is necessary to study the effect of overdose application of common pesticides on plants. In this study, the effects of different concentrations recommended and double of the recommend dosages of Arrivo 25 EC on mitosis and meiosis of *H. orientalis* were investigated.

MATERIALS AND METHODS

Plant Material and Arrivo 25 EC

The selected plant material healthy *H. orientalis* bulbs were obtained from the market. The insecticide used in the study was Arrivo 25 EC (250g/l Cypermethrin, $C_{22}H_{19}Cl_2NO_3$), which was produced and distributed by the company Hektaş.

Application of Arrivo 25 EC

The commercially maintained and selected *H. orientalis* bulbs were germinated for primary roots of 1–2 cm long in erlenmeyer flasks containing distilled water. The germinated primary roots were treated with three different concentrations of (%0.5, %1, %2.5 ml) Arrivo 25 EC. All experiments were carried out in three repetitions.

Mitotic Analysis

The flower buds were fixed first in Carnoy solution (3:1 alcohol-acetic acid) and hydrolyzed in 1 N HCl at 60°C for 5–10 minutes. They were, then, crushed in a 2% orcein stain in 45% acetic acid and the slides were examined immediately. The mitotic frequency was determined by examination of 1000 cells per slide.

Detection of Chromosomal Abnormalities

To investigate the abnormality percentages (chromosomal bridges, lagging chromosomes, chromosomal fragments, etc.) in different stages of mitosis and meiosis I, II, abnormal cells were counted and the percentage of abnormal cells was determined in each phase. Chromosomal abnormalities were evaluated separately in all phases of mitosis and photographic data was obtained using an Olympus BX51 photomicroscope.

Statistical Analysis

The statistical analyses of data were carried out using SPSS for Windows version 11.0 statistical software (SPSS Inc., Chicago, USA). Statistically significant differences between the groups were compared using both one-way analysis of variance (ANOVA) and Chi-Square Test. The data were displayed by mean $\pm$ standard deviation (SD). P-values less than 0.05 were considered statistically significant.

RESULTS AND DISCUSSION

Mitotic index (MI), which reflects the frequency of cell division, is an acceptable measure of cytotoxicity for all living organisms. If the mitotic index decreases below 22% of the control, it can cause lethal effects on the test organism (Cavusoglu et al., 2011). This study demonstrated the use of higher concentrations of each different Arrivo 25 EC concentration in the various phases of mitosis. Cytotoxicity was defined as decrease in mitotic index revealed the mitodepressive effect of Arrivo on mitotic index (MI) of *H. orientalis*. While treating seeds with different concentrations of Arrivo 25 EC, we observed that Mitotic Frequency Percentage decreased while the concentrations increased for each concentration of Arrivo 25 EC. The mitotic index of 0.5 ml and 2.5 ml % concentrations was slightly higher compared to control. The Arrivo 25 EC concentrations used had a negative effect on mitotic division. The mitotic frequency was 15.3% in the control group and decreased to 12.9% at 0.1ml concentration, 10.8% 0.5 ml concentration and 8.0% at 2.5 ml concentration Arrivo 25 EC (Table 1). The Arrivo 25 EC concentrations used had a negative effect on mitotic division. In high Arrivo 25 EC concentration, mitotic frequency reduced to almost half of that of the control (Figure 1), which affirmed the relationship between this parameter and morphological characters as previously reported by Abderrhman (1998), Abou Elkheir (1992) and Alam et al. (1987). This increase may due to shortening the duration of mitotic cycle and enhancing the interphase cells that entered the subsequent division stages (Haroun & Al shehri 2001) or because of the prompting of the synthesis of DNA in dividing cells (Badr et al., 1985; Chand & Roy 1981). Inhibition of mitotic activities was often used for tracing cytotoxic substances.

Table 1. The effect of Arrivo 25 EC concentrations on mitotic frequency percentage

Concentration (ml)	Cell numbers	Prophase	Metaphase	Anaphase	Telophase	Divided Number of Cells	Mitotic Frequency Percentage (%)
Control	1000	79	16	21	37	153	15.3
0.1	1000	58	21	13	37	129	12.9
0.5	1000	53	15	13	27	108	10.8
2.5	1000	45	11	11	13	80	8.0

Figure 1. Mitotic frequency percentage in *H. orientalis* treated and control groups in root meristematic cells.

We also examined the mitotic abnormality percentages and frequencies for prophase, metaphase, anaphase and telophase for different concentrations at different hours (Table 2). We observed that mitotic abnormality increased for all measurements as the concentration amount increased. For example, for prophase, the abnormality percentage was 0% in the control but increased to 66.6% at 0.1 ml, 66.6% at 0.5 ml and 2.5 and 100% at 2.5 ml concentration Arrivo 25 EC.

Table 2. The effect of Arrivo 25 EC concentrations on the mitotic abnormality percentage and frequencies

Concentration %ml	Prophase I			Metaphase I			Anaphase I			Telophase I		
	N	A	%A	N	A	%A	N	A	%A	N	A	%A
Control	2	-	-	3	79	96.3	-	4	100	2	-	-
0.1	1	2	66.6	3	33	91.6	-	3	100	2	3	60
0.5	2	4	66.6	3	4	57.1	1	8	88.8	2	-	-
2.5	-	2	100	-	8	100	-	4	100	-	1	100

N; Normal cell, A; Abnormal cell.

Figure 2. The following common abnormalities were observed at 0.5 ml Arrivo 25 EC;

a) Chromosomal bridge in telophase, b) Picnotic nucleus, c) Multipolar anaphase
d) Multipolar metaphase. The abnormalities present are indicated by arrows.

It was determined that the chemical treatment (including Arrivo) had drastic impact on non-target insect species (Lovei & Sunderland, 1996). Detrimental effects of insecticides, acaricides or other chemical compounds on pollen germination, fruit set and/or yield were reported on apple (Mayer & Lunden, 1986; Bound & Jones, 2004; Nichols et al., 2004). Mayer and Lunden (1986) noted that acaricides used during bloom influenced pollen viability of apple and pear.

The 0.5 ml Arrivo 25 EC concentration were found in *H. orientalis* Chromosomal bridge in telophase, Picnotic nucleus, Multipolar anaphase, Multipolar metaphase (Figure 2).

The 2.5 ml Arrivo 25 EC concentration were found in *H. orientalis* Chromosomal bridge in telophase, Laggard chromosome in anaphase, Normal mitosis, Multipolar anaphase (Figure 3).

The 2.5 ml Arrivo 25 EC concentration were found in *H. orientalis* at meiosis I Laggard chromosomes in interphase, abnormal prophase, chromosomal bridge in anaphase, chromosomal bridge and micronucleus formation in telophase (Figure 4).

The 2.5 ml Arrivo 25 EC concentration were found in *H. orientalis* at meiosis II Picnotic nucleus, deformations in nuclei, chromosomal bridge in anaphase, micronucleus, Laggard chromosome, chromosome decondensation and micronuclei formation (Figure 5).

To investigate the effects of toxic substances applied to plant organisms, it is important to investigate the chromosome anomalies and mitotic index in the root meristematic cells. The mitotic index reflects the frequency of cell division and is used as an important parameter in determining the rate of root development (Jiang et al., 2000). The mitotic index decrease is defined as the lethal effect (Antonsie-wiez, 1990), which falls below 22% when compared with control groups, and the sublethal effect, which falls below 50% (Panda & Sahu, 1985). These values were defined by the researchers as cytotoxic limit values (Sharma, 1983). Schulze and Kirscher (1996) have claimed that the mitotic index depression is due to the fact that genotoxins with mitochondrial deprivation have the power to block DNA and nucleoprotein synthesis. El-Ghamery et al. (2000) demonstrated that mitochondrial inhibition is caused by blockage of G1 phase and suppression of DNA synthesis in S phase. Based on the results of their study, Bal (1995) suggested that mitotic index depression may be due to mitotic cycling, as a physiological response to unprotected cells against toxic chemical agents such as energy pathway, inhibition of protein, RNA and DNA synthesis. Kaymak (2005) suggested that various chemicals might be the result of the influence of microtubules on the chromosomes, which are essential proteins that provide the formation of spindle fibers necessary for mitosis. Eun et al. (2000) noted that chemical agents altered microtubule organization and indirectly inhibited mitotic activity.

Changes in the number and structure of chromosomes occur as a result of abnormal placement of chromosomes by the effect of toxic chemical agents. Examples of loss of chromosome include backward chromosome, adhesiveness, multipolarity and c-mitosis. Materials that cause fractures in chromosomes can cause changes in chromosome bridge formation or chromosome structure (Leme & Marin-Morales, 2009; Radic et al., 2010).

Backward chromosomes might form as a result of the disorders which occur in the organization or functions of the spindle threads (Yıldız et al., 2009; Fındıklı & Türkoğlu, 2010; Türkoğlu, 2012); anaphase bridge might form as a result of the translocation with unequal chromatin changes and presence of chromatin breakage (Liman, 2013); c-mitosis formation is seen as a result of degradation of spindle yarns (Yoshida et al., 1983); hyperhomologous chromosomes arise as a result of backwardness in chromosomes, inadequacy of chromosomal motions or irregularities in the signaling process, depending on the state of the spindle fibers being affected; multipolarity emerges as a result of partial influences of spindle fibers (Ahmad 1992); whereas adhesion in chromosomes occurs as a result of physical adhesion of chromatin proteins. Moreover, it has been reported that bridge formation may occur during chromosomal adhesions, disentric chromosome formation, merger in sister chromatids and chromosomes moving towards the poles. In addition, fragments of broken chromosomes can cause micronucleus formation and loss of genetic material (Topaktas & Rencuzogullari, 1995).

Figure 3. The following common abnormalities were observed at 2.5 ml Arrivo 25 EC; a) Chromosomal bridge in telophase, b) Laggard chromosome in anaphase, c) Normal mitosis, d) Multipolar anaphase. The abnormalities present are indicated by arrows.

Figure 4. The following common abnormalities were observed at 2.5 ml Arrivo 25 EC at meiosis I. a) Laggard chromosomes in interphase, b) Abnormal prophase, c) Chromosomal bridge in anaphase, d) Chromosomal bridge and micronucleus formation in telophase. The abnormalities present are indicated by arrows.

Figure 5. The following common abnormalities were observed at 2.5 ml Arrivo 25 EC at meiosis II. a) Picnotic nucleus, b) Deformations in nuclei, c) Chromosomal bridge in anaphase, d) Micronucleus, e) Laggard chromosome, f) Chromosome decondensation and micronuclei formation. The abnormalities present are indicated by arrows.

As stated before, decreases in the mitotic index, increases in the numbers of abnormally dividing cells and increases in chromosomal abnormalities are caused by the inhibition of energy pathway, protein, RNA and DNA synthesis, the alteration of the microtubule organization and the synthesis mechanism of the main proteins that provide the formation of spindle spinning, affecting genes or gene products that regulate cell division control points (Yuksel & Aksoy 2017; Aksoy et al., 2012). Based on these results, we can infer that Cypermethrin acts like a cytotoxic agent.

Occurrence of chromosomal bridges, laggard chromosomes and multipolar anaphases clearly shows the accumulated effects of Arrivo on the spindle formation. The phenomenon of chromosome stickiness indicates the toxicity of Arrivo and occurrence of breaks and bridges show that it is a potent clastogen. In sum, the present study shows that Arrivo, commercial formula of Cypermethrin, is genotoxic because this pesticide induced chromosome abnormalities in *H. orientalis*. Since, mitotic index is decreased, Arrivo has high cytotoxic effects. As a result of cytological studies, it can be said that Cypermethrin is effective both in chromosome organization and DNA level. Hence, more care should be given to the application of Arrivo in agriculture, in countries where it is widely used.

ABSTRACT

Wild flora and agricultural crops are faced with a variety of environmental stress factors culminating in considerable economic losses worldwide. Aluminum toxicity is one of the important abiotic stresses limiting plant growth. Aluminum (Al) is the third most abundant element in the soil, after oxygen and silicone; comprising approximately 7%. Whereas it exists primarily in the form of insoluble aluminosilicates or oxides, the complex Al becomes solubilized in acidic soils (< pH 5.0). After Al absorption, the toxicity effects root growth adversely resulting in poor uptake of water and nutrients. The root apex consisting root cap, meristem and elongation zone has a major role in Al-penetration mechanism and accumulates more Al. The common effects of Al are thick, cracked and stubby roots, inhibited cell and root elongation, increment in cell wall rigidity, callose formation, alteration of plasma membrane and cytoskeleton, production of oxygen-free radicals, and interaction with DNA. These cellular alterations lead to oxidative stress and programmed cell death. Programmed cell death (PCD) is genetically controlled and highly regulated cell disassembly, which appears during development or under stressful conditions. During PCD, some common cellular characteristics such as cell shrinkage, vacuolization, cytochrome c release from mitochondria, specific protease activation, chromatin condensation and DNA fragmentation become apparent both in plants and animals. A few researchers indicate that Al toxicity also causes PCD. It has been known that some of the plant species have self-tolerance metabolism against Al toxicity. However, Al toxicity may be alleviated by exogenous application of organic and inorganic compounds. Even if many researchers have performed to understand the mechanism of Al toxicity and tolerance, it has not yet been fully characterized because of the complicated chemical nature of Al. Moreover, the underlying molecular, genetic and

physiological features are still not clear. Although this review will describe Al toxicity and PCD principles generally, our aim is to focus especially on the mechanisms of Al-induced PCD which have been largely ignored with the goal in mind for environmental monitoring.

Keywords: acid soil, aluminum toxicity, aluminum tolerance, plant, programmed cell death, root

INTRODUCTION

Although aluminum (Al) is one of the most abundant and prevalent mineral in the earth's crust (7%), it is not assumed as an essential element for living organisms (Matsumoto, 2000; Abate et al., 2013). Al, as an abiotic stress factor, is one of the major plant growth-limiting factors at low pH (acid) soils. It has been thought that 67% of the world's potential farmable lands have acid soil below pH 5.0 and face to Al toxicity (Kochian et al. 2004; Abate et al. 2013; Ma et al. 2014). Al is a non-toxic constituent in the neutral or weakly acidic soils as insoluble aluminosilicates or oxides, but when the soil turns out to be more acid, complex Al is solubilized into phytotoxic forms. $\text{Al}(\text{H}_2\text{O})_6^{3+}$ dissolve to Al^{3+} ion and it is the most toxic and dominant form in low pH soils (Matsumoto, 2000; Vardar and Ünal, 2007). Whereas occurrence of acidic soil is a natural occurrence in tropical and subtropical zones such as South America, Central Africa and Southeast Asia, it is also a critical environmental problem in temperate zones. In industrial regions such as USA, Canada and Europe countries environmental pollution and acid rains raise the solubilized Al^{3+} ions in the soil (Vitorello et al., 2005). Soil acidity is also attributed to exhaustive agriculture, inappropriate farming and over leaching with basic actions. As a broad notion, acid soil fertility is regressed by the reason of toxic (Al, Cd and Mn) and deficient minerals (P, Ca, Mg and Mo). It has been stated that solubilized Al presents at the range of 10–100 μM in acid soils, and regarded as a primary constraint for crop production. Researchers also evidenced that Al adversely affect plant growth and development within a few minutes even at low micro-molar doses in acid soils (Eswaran et al., 1997; Ciamporova, 2002; Vitorello et al., 2005; Vardar and Ünal, 2007; Abate et al., 2013).

Considering the whole plant, toxic Al ions have adverse effects such as structural and anatomical deformation, chlorosis and necrosis. Besides, reduction in total leaf number, decreased photosynthetic activity due to chlorosis, reduction of stomatal aperture, regression in shoot biomass, inhibition of root growth also occur under Al stress. Although Al toxicity symptoms are also apparent in the shoots, the roots are the first affected organ. Several researchers indicated that Al-induced root growth inhibition causes poor uptake of soil water and mineral elements such as Ca, Mg, K, Fe and P resulting in decreased yield and crop quality (Jones and Kochian, 1995; Miyasaka et al., 2001; Delhaize et al., 2004).

Several studies prove that root apex (consisted of root cap, meristem and elongation zone) as a first target plays a critical role in Al penetration. This root region also absorbs more Al (Matsumoto, 2000). As a result of Al uptake morphology of root apices change to swollen, cracked, stubby and stiff appearance (Vardar et al., 2006). Reduction in fine branching and root hairs are also evident (Ciamporova, 2002). Root growth inhibition is the most noticeable and evident characteristics of Al toxicity (Singh et al., 2017). It has been considered that

reduction of root growth is the consequence of interfered cell elongation and expansion, prior to arrested cell division (Frantzios et al., 2001; Ciamporova, 2002; Vardar et al., 2007). Several researches revealed that plant genotype, cell/tissue type, pH and content of external solution (types of chelators, concentrations of Ca^{2+} and other cations) are decisive on the severity of Al toxicity (Kinraide and Parker, 1987). Table 1 presents some sample of Al toxicity researches performed in different plant species and cell types with different concentration and exposure time.

Al ions interact with cell wall (apoplastic target), plasma membrane and cytosol (symplastic target) within seconds to minutes resulting toxic symptoms (Kochian et al., 2005). It has been identified that Al binds and accumulates in root apoplasm predominantly. Positive charged Al has the ability of binding negatively charged carboxyl groups of pectin building cross-links in cell wall (Blamey et al., 1993; Singh et al., 2017). Al also binds to apoplasmic side of plasma membrane. These reactions cause to the displacement of other positively charged ions such as Ca^{2+} responsible for strength of cell-wall. Al toxicity also induces rapid callose (β -1,3-glucane) synthesis and accumulation on plasma membrane integrating into apoplasm (Tabuchi and Matsumoto, 2001). Callose synthesis which is one of the important markers of Al toxicity may assists plant to manage with Al toxicity by blocking the plasmodesmata. Thus, callose plugs block movement of water and solutes through cell to the apoplasm causing reduction of nutrient supply (Blamey, 2001). Alterations of structural and mechanical functions of cell wall, as a result of strong and rapid binding of Al, cause more rigid and reduced mechanical extensibility. Eventually, disrupted growth orientation together with unusual periclinal divisions occurs (Kochian et al., 2005).

Because of its negatively charged surface, plasma-membrane is one of the important targets for Al^{3+} (Kinraide et al., 1998). It has been reported that Al^{3+} binds to both phospholipids and proteins of the membrane altering the structure by inducing lipid peroxidation (Panda et al., 2009). Al has approximately 560-fold more affinity than other positively charged ions (e.g., Ca^{2+}) for the choline head of phosphatidylcholine. Al forms positively charged bridges between head groups of the phospholipid in the plasma membrane resulting in displacement of other cations (Akeson and Munns, 1990; Singh et al., 2017). The positively charged layer changes the movement of ions through the plasma membrane. This situation commonly results in inhibited cation movement and increment in anion movement (Nichol et al., 1993). Consequently, the structure and charge of plasma membrane, phospholipid fluidity altered leading to perturbation of cellular homeostasis (Kochian et al., 2005). It has been also suggested that Al-induced cation displacement triggers callose synthesis (Gupta et al., 2013). Although the Al-specific carrier protein has to be discovered yet, it can interact with different channel proteins inhibiting the uptake of essential ions such as Ca^{2+} , K^{+} , Mg^{2+} and NH_4^{+} . Moreover, Al significantly disrupts H^{+} gradient altering the ionic condition and balance of root cells (Piñeros and Tester, 1997; Kochian et al., 2005; Singh et al., 2017).

The cytoskeleton (microtubules, actin filaments and intermediated filaments) is one of the potential targets for Al in the cell causing damage in cytoskeletal dynamics. Cytoskeletal stabilization is important during cell-wall biosynthesis and cell division, principally. Al disrupts cytoskeletal dynamics and stabilization via directly interacting cytoskeletal elements/subunits or altering their signaling cascades (Sivaguru et al., 1999). Researches also revealed that lateral cell swelling is the result of microtubule and actin filament disruption in their organization after Al exposure (Frantzios et al., 2001; Sivaguru et al., 2003). Moreover,

Al changes the signal transduction pathways affecting the whole plant. Protein phosphorylation and dephosphorylation are also regulated by Al induction (Matsumoto, 2000; Singh et al., 2017).

<i>N. tabacum</i> cv BY-2	Root and cell culture	Hydroponic culture and MS medium	4.5	50-100 μM AlCl_3	3 days	Kariya et al. 2018

Al has a genotoxic profile and long term Al exposure can lead detrimental effects on DNA composition and DNA replication by constructing more rigid double helix and chromatin structure. Many researchers observed that Al toxicity reduces mitotic index and increases abnormal chromosome movements which are related to Al-induced alterations in tubulin polymerization and depolymerization. Besides, chromosome laggards, bridges,

micronuclei and c-mitosis are revealed during Al stress (Silva et al., 2000; Frantzios et al., 2000; Vardar et al., 2011).

Al toxicity increases the production and accumulation of reactive oxygen species (ROS) in mitochondria, chloroplast and peroxisome (Kochian et al., 2004) which trigger oxidative damage in cell (Darko et al., 2004; Sharma and Dubey, 2007; Gupta et al., 2013). Under stress conditions various forms of ROS species ($O_2^{\cdot-}$, $\cdot OH$, $HO_2^{\cdot}$, H_2O_2 and 1O_2) are generated in plant cell inducing lipid peroxidation, DNA damage, protein denaturation, distribution of antioxidant enzyme balance, carbohydrate oxidation, pigment breakdown leading to programmed cell death.

ALUMINUM INDUCED PROGRAMMED CELL DEATH

In natural habitats, environmental stresses affect plants frequently because of being sessile organism. Excessive stress conditions, can damage wild flora and agricultural crops with regard to environmental and economic losses worldwide (Tuzhikov et al., 2011). Otherwise, plants have evolved alternative adaptive mechanisms to enable the survival of whole organism. Programmed cell death (PCD) is one of the adaptive mechanisms under extreme environmental stresses (Jackson and Armstrong, 1999; Drew et al., 2000). PCD can be described simply as a genetically regulated and coordinated cell elimination process in certain cells by specific proteases and nucleases during development and biotic–abiotic stresses (Wang et al., 2011; Vardar and Ünal, 2012; Wituszynska and Karpinski, 2013; Petrov et al., 2015).

PCD as a well-organized cell suicide process has common characteristics in eukaryotic cells such as shrinkage of cell, vacuolization, cytochrome c release from mitochondria to cytoplasm, specific protease activation, chromatin condensation, DNA fragmentation and finally breakdown of cellular contents (Qiao et al., 2003; Brighigna et al., 2006; Vardar and Ünal, 2008; Papini et al., 2011; Wang et al., 2012; Poor et al., 2013). Comparing plants and animals, plants have evolved their own pathways due to the existence of cell walls as a barrier. In dying plant cells, the cell wall prevents them from being phagocytosed by neighboring cells as it is in animals. Furthermore, among eukaryotic PCD forms rare conserved regulatory proteins or protein domains have been identified at the molecular level (Danon et al., 2004).

Plant growth and development are mediated and regulated by endogenous factors under environmental stress. One of these endogenous factors is ROS acting as signaling molecules (Nath and Lu, 2015). The ROS are generated as byproducts of respiration and photosynthesis in cellular organelles such as chloroplasts, mitochondria and peroxisomes. Superoxide anion ($O_2^{\cdot-}$), hydroxyl radical ($\cdot OH$), hydrogen peroxide (H_2O_2) and singlet oxygen (1O_2) are the most common produced free and non-radicals (Sharma et al., 2012). Lower doses of ROS act as a secondary signaling molecule that mediates the responses toward stress. But higher concentrations of ROS induce oxidative stress which damage macromolecules such as DNA, RNA, protein and lipid leading to PCD (Woo et al., 2013; Coll et al., 2014; Petrov et al., 2015). Even if there are a lot of researches on PCD, the relation between abiotic stress-induced as well as Al stress-induced PCD is still unclear and need to be investigated in molecular aspects.

There are several studies concerning increase of Al-induced ROS and antioxidant enzyme activities which are their scavengers in different plant species. In general, lipid peroxidation, superoxide dismutase, catalase, glutathione and guaiacol peroxidase activities increase in dose and/or time dependent manner (Boscolo et al., 2003; Vardar et al., 2011; Malekzadeh et al., 2015; Nogueirol et al., 2015). Lately, antioxidant enzyme activities and related defense gene expression in two passion fruit cultivars were also evaluated by Pretti et al. (2018). According to their results Al induced oxidative stress and increased both activity and gene expression of catalase and superoxide dismutase characterized by RT-PCR (semi-quantitative reverse transcription-polymerase chain reaction).

It has been revealed that under stress conditions ROS weaken binding of the cytochrome c (cyt c) to the inner mitochondrial membrane and cause its diffusion to the intermembrane space. At the same time, ROS also provoke the mobilization of Ca^{2+} ions from the endoplasmic reticulum to mitochondria. Ca^{2+} ions act as secondary signaling molecules and induce to reduce the mitochondrial membrane potential ($\Delta\Psi_m$). Subsequently the mitochondrial permeability transition pores (MPTP) are opened in the outer mitochondrial membrane permitting cyt c pass into the cytosol (Ott et al., 2007; Williams et al., 2014). The cyt c extrusion triggers more ROS generation in the mitochondria amplifying the signal. According to the researches, enhanced ROS generation and cyt c release trigger caspase-like activities in plants (Gunawardena and McCabe, 2015).

Li and Xing (2011) investigated possible mechanisms of PCD induced by Al. The researchers used to monitor the behavior of mitochondria and increase of caspase-3-like activity. They detected a quick burst of mitochondrial ROS, swelling of mitochondria, loss of MTP (mitochondrial transmembrane potential) and caspase-3-like activation prior to PCD in Arabidopsis. The researchers concluded that mitochondrial events such as swelling, generation of ROS and loss of MTP have critical roles triggering caspase-3-like activity and PCD providing a new perspective about Al-induced PCD mechanism.

Huang et al. (2014) reported that Al-induced ROS accumulation and PCD are closely related. According to their results 100 μM AlCl_3 caused ROS burst and up-regulation of *Rboh* and *COX* expression related to ROS mediation in peanut roots. Besides, the researchers also revealed increased MPTP opening, decreased $\Delta\Psi_m$, cyt c release from mitochondria to cytoplasm and caspase 3-like protease activity. The researchers concluded that Al induced PCD is regulated via a cascade of cellular events depending on mitochondrial pathway and ROS mechanism. Zhan et al. (2014) undertook a research to establish the role of mitochondria in Al-induced PCD in both Al-tolerant and sensitive peanuts. It has been reported that increase in mitochondrial ROS production and MDA were enhanced in two peanut cultivars. Besides, reduction of mitochondrial Ca concentration, opening of MPTP, collapse of $\Delta\Psi_m$ and cyt c release were more extensively in Al sensitive cultivar depending on Al concentration.

In animals, caspases regulate the PCD. Caspases are cysteine-dependent proteases and cleave their substrates after an Asp (aspartic acid) residue (Cai et al., 2014). It has been indicated that there are no caspase homologs in plant genomes, but caspase-like proteases and caspase-like activities were also identified in plants recently (Rocha et al., 2017). Synthetic animal caspase substrates were also used to determine caspase-like activities in plant PCD types (McStay et al., 2007; Ayturk and Vardar, 2015). In last decades, plant metacaspases are accepted as distant relatives of animal caspases (Uren et al., 2000). Metacaspases prefer to cleave their substrates after arginine (Arg) or lysine (Lys) as distinct from animal caspases

(Watanabe and Lam, 2005; He et al., 2008; Salvesen et al., 2016). Similar to caspases and metacaspases, vacuolar processing enzymes (VPEs) are also cysteine proteases (Hatsugai et al., 2004; Cai et al., 2014). VPEs cleave their substrates after an asparagine (Asn) residue distinct from caspases and metacaspases, but interestingly they also interact and cleave caspase-1 substrate (YVAD). Moreover, VPE activation repressed by inhibitor of synthetic caspase-1(ac-YVAD-CHO) (Sexton et al., 2007; Misas-Villamil et al., 2013). It has been reported that both metacaspases and VPEs have a regulatory role during environmental stress-induced PCD.

Kariya et al. (2013) investigated the role of vacuole in Al-induced PCD mechanism in *Nicotiana tabacum* L. cv BY-2 cell line. After 18 h Al treatment (0-150 μ M), cell growth and the integrity of plasma membrane were reduced, whereas VPE activity was increased dose dependently. Besides, morphological alterations of vacuole were also evident. They also observed that the presence of inhibitor of VPE (Ac-YVAD-CHO) suppressed the loss of plasma membrane integrity. The researchers evidenced that Al-induced VPE activity is controlled at transcriptional level, and loss of integrity of the plasma membrane and a loss of growth capacity are regulated by VPE activity. Lately Kariya et al. (2018) reported an increase in gene expression of *VPE1a* and *VPE1b*, but there were no change in *VPE2* and *VPE3* gene expression at tobacco roots after Al exposure.

Several studies using synthetic caspase substrates revealed caspase-like activities under Al stress conditions. Aytürk and Vardar (2015) indicated caspase-3, -8 and -9 like activities in triticale, barley, rye and oat roots after 100 μ M Al exposure. Similarly, Yao et al. (2016) used synthetic caspase-1, -2, -3, -4, -5, -6, -8 and -9 substrates in Al tolerant and Al sensitive peanut roots after 100 μ M Al. The results demonstrated that especially caspase-1 and -3 activities showed the highest activity in both cultivars. Besides, Al toxicity caused nuclear degeneration and DNA fragmentation.

DNA fragmentation originates from internucleosomal DNA cleavage by specific proteases and nucleases. Whereas ultrastructural features such as cell shrinkage and vacuolization points PCD (Liu et al., 2018), DNA fragmentation analysis is the most sensitive parameter of PCD. DNA fragmentation can be monitored by using TUNEL (Terminal deoxynucleotidyl transferase dUTP nick end labeling) reaction histochemically, comet assay, flow cytometry and laddering on the agarose gel.

In one of the early studies assessing Al-induced DNA fragmentation, barley roots were exposed to Al within a range of 0.1–50 mM (Pan et al., 2001). It has been revealed that Al concentrations between 0.1–1 mM induced clear DNA fragmentation, but the higher concentrations (10–50 mM) caused necrotic DNA smear. Comet assay can be also used to indicate DNA damage by measuring the DNA tail. Achary et al. (2008) demonstrated Al-induced breaks in double stranded DNA in *Allium cepa* roots by comet assay. Subsequently, Achary and Panda (2009) also evaluated Al-induced DNA damage in a range of 200-800 μ M Al in *A. cepa*. Achary et al. (2012) revealed a dose-dependent DNA damage in *H. vulgare* roots with different concentrations of Al (2.5, 5 and 10 mM). Furthermore, in peanut (*Arachis hypogaea*) roots 100 μ M AlCl_3 induced DNA fragmentation (Huang et al., 2014) revealed time dependent DNA damage by comet assay in wheat, rye and triticale roots after 100 μ M AlCl_3 exposure. Similarly, Vardar et al. (2016) demonstrated DNA fragmentation by agarose gel electrophoresis in wheat, oat, rye and triticale. Otherwise, Jaskowiak et al. (2018) reported Al-induced DNA fragmentation by TUNEL reaction in barley roots. The researchers also tested cell cycle profile and DNA integrity after Al exposure by flow cytometry. According to

the results, Al reduced the frequency of S phase cells and altered the cell cycle profile significantly. The delay of mitotic divisions caused increased cells frequency in G2/M phase.

Although there are several researches on Al-induced DNA damage, Al induced DNA methylation and polymorphism on LTR retrotransposons were also reported recently (Guo et al., 2018; Taşpınar et al., 2018). The researchers suggested that transposon polymorphism and methylation may be a part of the defense mechanism under Al stress.

ALUMINUM TOLERANCE AND ALLEVIATION

It has been known that some plant genotypes are Al tolerant. Because of the agronomic importance of Al resistance, the underlying molecular and physiological principles have become an important research area. The mechanisms of Al tolerance can be regulated both exclusion of Al from the root apex or intracellular tolerance of Al being transported into the symplast (Kochian et al., 2005).

It has been known that Al as a very reactive cation tends to form strong complexes with oxygen donor ligands. Several researches revealed that root exudates or mucilage (glucose, galactose, arabinose and uronic acids) make complexation with Al via chelation or direct binding preventing the accumulation of Al in apoplast or symplast (Barceló and Poschenrieder, 2002). Root apex secretes phosphate, carboxylate, phenolic substances, pectates, mucopolysaccharides and/or siderophores which can make complexes with Al ions (Winkler et al., 1986). Chelation of Al blocks the activity of Al ions preventing their binding to Al targets such as cell wall and plasma membrane. Although roots secrete different variety of exudates, carboxylates such as malate and citrate are most commonly detected (Barceló and Poschenrieder, 2002).

Whereas root exudates seem to be the most important Al tolerance mechanism restricting Al transport to the upper organs, several plant genotypes may tolerate high Al levels in their cell vacuoles or apoplast with ligands in an innocuous form by complexation and detoxification of Al. For example, *Hydrangea macrophylla* leaves accumulate Al making complex with citric acid and their sepals turn red to blue due to accumulated Al concentration. This situation also related to soil acidification resulting in Al dissolution (Takeda et al., 1985). The stated internal detoxification mechanism occurs with Al chelation in the cytosol and storage in the vacuole as Al-carboxylate complex.

Recently several types of ameliorating chemicals against Al toxicity have attracted attention in breeding crops because of their agronomic importance. Based on this, many researchers experienced some chemicals exogenously which are tend to make strong complexes with Al (Table 2). The most prominent chemicals are citric, oxalic, malic, oxalic and tartaric acids which are oxygen donor ligands (Hue et al. 1986; An et al., 2014). Yalçın and Vardar (2016) reported that both pre-treatment and co-treatment of salicylic acid alleviated Al toxicity, possibly stimulating the roots to secrete organic molecules such as citrate which are able to make chelation with Al. Pandey et al. (2013) alleviated Al toxicity applying Ca, Mg and salicylic acid. According to their results, the exogenously supplied chemicals suppressed ROS mediated oxidative stress, but salicylic acid was more effective in alleviation than Ca and Mg. Besides Chen et al. (2013) investigated the possible role of H₂S against Al toxicity. The researchers revealed that H₂S reduced Al accumulation and ROS

generation by increased antioxidant enzyme activities. They also indicated that H₂S increased both citrate secretion and citrate transporter gene expression. Wang et al. (2013) determined the alleviation effect of indol-3-acetic acid through reducing Al uptake and stimulating malic acid secretion in wheat roots. Moreover, it has been reported that silicone reduces Al uptake and ameliorates Al toxicity by making complexes with Al ions (Kopittke et al., 2017).

Table 2. Some ameliorating chemicals against to Al toxicity

Plant material	Plant organ	Growth solution	Al conc.	Alleviation agent	Reference
<i>Oryza sativa</i>	Root, shoot	Direct exposure	0.5 mM AlCl ₃	1 mM CaCl ₂ 0.25 mM MgSO ₄ 60 µM Salicylic acid	Pandey et al., 2013
<i>Triticum aestivum</i>	Root	CaCl ₂	50 AlCl ₃	25 µM Indol acetic acid 5 µM Niflumic acid 5 µM 2,3,5-triiodobenzoic acid	Wang et al., 2013

<i>T. aestivum</i>	Root	Nutrient solution	100 µM AlCl ₃	125- 625-2500 µM CaCl ₂	Hossain et al., 2014
<i>Brassica napus</i>	Shoot, root, leaves	Hoagland solution	0.1-0.2-0.3-0.6-1 mM AlCl ₃	0.3 mM NaHS	Ali et al., 2014
<i>Citrus grandis</i>	Shoot, root	Nutrient solution	1.2 mM AlCl ₃	2,5-20 µM H ₃ BO ₃	Zhou et al., 2015
<i>T. aestivum</i>	Shoot, root	Oxisol slury	-	Silicon (Si) rich biochar	Qian et al., 2016
<i>Hordeum vulgare</i>	Root	Direct exposure	20 µM AlCl ₃	5 -10 µM Salicylic acid	Yalcin and Vardar, 2016
<i>Borago officinalis</i>	Root, shoot	Hydroponic solution	20-60 mM AlCl ₃	0.2-1-2 mM Si	Delavar et al., 2016
<i>Glycine max, Sorghum bicolor</i>	Root	Direct exposure	5-10-25-30 µM AlCl ₃	2 mM Si	Kopittke et al., 2017
<i>O. sativa</i>	Root, shoot	Nutrient solution	0.19 mM Al	0.11 mM Si	Freitas et al., 2017
<i>O. sativa</i>	Root	CaCl ₂ solution	50 µM Al	10 µM La 400-600 µL/L CO ₂	Zhu et al., 2017
<i>Vigna radiata</i>	Leaves	Direct exposure	0.5 mM AlCl ₃	0.3 mM spermidine	Nahar et al., 2017
<i>H. vulgare</i>	Root, shoot	Hoagland solution	2-4-6 mM	2 mM Ascorbic acid 250 µM Salicylic acid	Shahnawaz et al., 2017
<i>Trifoliate orange</i>	Root	Direct exposure	400 µM AlCl ₃	10 µM H ₃ BO ₃	Riaz et al., 2018
<i>O. sativa</i>	Root	CaCl ₂ solution	30-50-100 µM AlCl ₃	1-2-5-10 µM NaHS	Zhu et al., 2018
<i>T. aestivum</i>	Root	CaCl ₂ solution	30 µM AlCl ₃	0.1-0.3-0.5 mM glucose oxidase 100 µM NO scavenger 100 µM diphenylene iodonium 5 mM dimethylthiourea 100 µM nitrate reductase 100 µM nitric oxide synthase	Sun et al., 2018

It has been known that polyamine (putrescine, spermidine, spermine) accumulation has a correlation with stress tolerance and adaptation (Nahar et al., 2017). Based on this, Yu et al. (2016) indicated a different mechanism on the alleviation of Al toxicity by using putrescine. The researchers revealed that putrescine induced on ethylene synthesis mechanism and decreased ethylene production alleviating root growth inhibition under Al stress conditions. Similarly, Nahar et al. (2017) reported alleviating effects of spermidine in mung bean seedlings under Al stress. The researchers also suggested that polyamines might have roles in regulating the antioxidant enzyme activities to decrease oxidative stress during Al stress.

In conclusion; Al toxicity especially in acidic soils has adverse effects on plant growth and development, as a result of this the productivity of crop reduces. Although the toxic effects of Al are well documented, the molecular signaling mechanism of Al toxicity is not clear. Besides, there is limited studies on Al-induced PCD and needs more detailed and sensitive research. To identify the Al toxicity and tolerance mechanism may help to improve Al tolerant varieties. Although several researches performed to mitigate Al toxicity using several types of chemicals, their alleviation mechanisms are still need to be clarified. Beside the Al tolerant varieties, proven chemicals might be used to ameliorate the adverse effects of Al to enhance the crop quality.

ACKNOWLEDGMENT

ABSTRACT

The brain is a very complex system of millions of nerve cells and consists of anatomically and functionally independent structures, all of which having many functions to control living organisms. The complexity of the brain tissue arises from its heterogeneity, distinct structural ordering, chemical composition and functional activity. Due to such complexity, region specific investigations of brain tissue may have prominent importance for identification of pathological conditions. In the present study, whole brains of Wistar rats and different brain regions such as right-left hemisphere, hippocampus and cerebellum were comparatively analyzed by Fourier transform infrared (FT-IR) spectroscopy. Within the scope of detailed spectral analysis, the frequency and areas of some specific modes such as olefinic, CH₂ asymmetric and symmetric, amide I, C=O and PO₂⁻ asymmetric stretchings were evaluated. In addition, the bandwidths of CH₂ asymmetric and symmetric bands were analyzed. Also, olefinic = CH/lipid, CH₂/lipid, lipid/protein ratios were calculated. Thus, differences in parameters such as protein and lipid amounts, lipid packing and lipid fluidity were observed. As a result, corresponding findings support that FT-IR spectroscopy can be successfully applied for comparative analysis of distinct parts of the same tissue.

Keywords: brain, hemisphere, cerebellum, hippocampus, FT-IR

INTRODUCTION

The brain serves as the central organ of the nervous system; and together with the spinal cord, it constitutes the central nervous system in all vertebrates and most invertebrates. The brain controls most of the activities of the body such as processing, integration, and coordinating the information as well as receiving data from sensory organs and making decisions as to the instructions sent to the rest of the body (Krafft et al., 2006; Hackett et al., 2011). As having a very important role for most of the animals including humans, the brain tissue represents very complex structure with varied anatomic areas.

In general, the brain consists of right and left hemispheres, which results in hemispheric asymmetry defined as the presence of functional, anatomic or neurochemical differences between distinct hemispheres in a variety of species including rodents and humans (Reddon et al., 2009). (Hering-Hanit et al., 2001; Avci et al., 2008; Gökçer et al., 2012). Although two hemispheres are specialized in different functions, they are not isolated from each other, and research has focused on how they cooperate. Molecular and functional imaging techniques have revealed evidence of neurochemical asymmetries in brain and provided information about the relationship between brain lateralization and animal behavior and function (Sang et al., 2015).

A major component of the brains of humans and other vertebrates is the hippocampus located in the medial part of the temporal lobe extending along the temporal horn of the lateral ventricle (Songur et al., 2001; Spring et al., 2009; Spasojevic et al., 2013; İzci et al., 2015). The hippocampus belongs to the limbic system. Despite its close relationship with many other regions of brain makes hippocampal function difficult to define, it plays important roles in the consolidation of information from short-term memory to long-term memory, and in spatial memory that enables navigation (Yassa et al., 2011). Since different neuronal cell types are organized into layers in the hippocampus, it has frequently been used as a model system for studying neurophysiology, therefore; this region is the most studied one on compared to other brain regions.

The second major part of the brain is the cerebellum, which consists of two small half-cylinders attached to the back of the brain and at the front of the spinal cord. It is located in the posterior fossa and occupies 10% of the brain's volume (Derman et al., 1986). This specialized part is well-known for its role in coordinating motor output and adapting involuntary repetitions to support sensory pre-defined hat-based learning (Parmar et al., 2018) and in motor, cognitive and behavioral development as obtained from the evidence from the fetal, neonatal and pediatric populations (Andreottia et al., 2018).

Regional differentiation of brain tissue results from region specific structural and functional variations of biomolecules being major building blocks of brain (Krafft et al., 2006; Hackett et al., 2011). Thus, the investigation of such alterations depending on distinct parts of the brain can be pivotal for understanding of the mechanisms of different diseases and disorders. (Samuel et al., 2008; Engel et al., 2013; Dixit et al., 2016). For this purpose, infrared (IR) spectroscopy is very suitable for analysis of brain tissue due to its ability in detection of the changes on content, structure and dynamics of biomolecules in cells and tissues (Cakmak et al., 2012; Derenne et al., 2012; Nallala et al., 2013; Ozek et al., 2014; Turker-Kaya et al., 2016). IR spectroscopy does not require any staining or complicated sample preparation (Derenne et al., 2012; Turker et al., 2014a). An IR spectrum of a

biological sample is the sum of various contributions from lipids, proteins, carbohydrates, nucleic acids and all other chemical species (Carmona et al., 2008; Miller et al., 2013; Ozek et al., 2014; Turker et al., 2014a,b). The intensities and/or areas provide quantitative information, peak positions relate to physical states of molecules, and bandwidth gives dynamic information (Severcan et al., 2005; Carmona et al., 2008; Miller et al., 2013; Ozek et al., 2014; Kumar et al., 2014; Turker et al., 2014a,b; Turker-Kaya et al., 2016). Due to such advantages, FT-IR spectroscopy has been increasingly employed to investigate molecular variations between different tissues and alterations induced by drugs, and even disease states which are not easily detectable by morphological methods in cells and tissues (Berger et al., 2010; Leskovjan et al., 2010; Cakmak et al., 2011; Bozkurt et al., 2012; Travo et al., 2012; Bellisola et al., 2012; Turker et al., 2014a,b; Turker-Kaya et al., 2016).

In the present study, we aimed to analyze left and right hemisphere, hippocampus and cerebellum regions of rat brain tissue in comparison to whole brain by FT-IR spectroscopy as similarly performed in our previous studies (Turker et al., 2014a,b; Turker-Kaya et al., 2016; Turker-Kaya et al., 2017). We monitored the relative changes in lipid and proteins content, membrane lipid packing, membrane fluidity, and lipid peroxidation products (LPPs), all of which are very important parameters for proper functioning of brain.

MATERIAL AND METHODS

A. Animal Experiments

Adult Wistar rats were used for animal experiments carried out at Kocaeli University/Turkey. The animals were kept in a constantly warm room for 12 hours in the light-12 hour dark cycle with 60% relative humidity. The rats were decapitated and their brains removed out under deep ether anesthesia. The dissected brains were separated into 4 groups as whole brain (WB, $n = 7$), left hemisphere (LH, $n = 6$), right hemisphere (RH, $n = 6$), hippocampus (HP, $n = 6$) and cerebellum (CR, $n = 6$). The removed brain tissues were stored at -80°C deep freeze till spectroscopic analysis. All procedures involving animals were in compliance with the European Community Council Directive of 24 November 1986, and ethical approval was granted by the Kocaeli University Ethics Committee (Number: 2017/091 and 2018/040HD, Kocaeli, Turkey).

B. FT-IR Spectroscopy Studies

For sample preparation, earlier studies were followed (Elilbol-Can et al., 2011; Turker-Kaya et al., 2016). Briefly, freeze-drying was performed using a (Labconco FreeZone®, Benchtop Freeze Dry System Model 77520) for 24 hours to remove excess water from brain tissues. Fully dried tissues were ground and each tissue powder (2 mg) was mixed with 100 mg of pre-dried Potassium Bromide (KBr). Later, the mixture was dried again in the freeze drier for 18 hours to remove all traces of remaining water. The prepared mixture was applied placed a pressure of 100 kg/cm^2 for 5 minutes to obtain a solid KBr pellet.

A Perkin-Elmer Spectrum One FT-IR spectrometer (Perkin-Elmer Inc., Norwalk, CT, USA) equipped with a MIR TGS detector was utilized for spectral acquisition. All spectra were recorded in the 4000–450 cm^{-1} region at room temperature. Each interferogram was collected with 100 scans at 4 cm^{-1} resolution.

Although special effort was given to produce same thickness of each KBr pellet, to minimize intra-sample variability which may be due to variations in experimental conditions, two independent pellets prepared by taking separate portions randomly from the same sample were scanned. The average spectrum of these two replicates giving identical spectra representing one animal was used in detailed data analysis.

C. Data Analysis

Each spectrum was analyzed by the Perkin Elmer Spectrum One program to reveal the spectral differences between the groups in terms of band area, band position and band width. The band positions (wavenumber) values were calculated by taking 70% of the peak height by evaluating the center of gravity of the bands. The bandwidth was calculated by converting peak height at 70% to cm^{-1} . The peak area was calculated as related to a linear baseline between two baseline points which involve the maximum peak height. The baseline point was identified according to start and end points of the peak. Later, the corrected area which is the area between the spectrum and the marked baseline within the marker bar limits was found the peak area value of the peak of interest.

Taking possible interference due to detectable variability of sample thickness into consideration, area ratios of some specific IR modes were also evaluated to approximate content changes in biomolecules. The lipid/ protein ratio was obtained by proportioning the total area under the CH_2 asymmetric and the CH_2 symmetric stretching (2925 cm^{-1} and 2852 cm^{-1}) bands to the total area under the bands amide I and amide II (1645 cm^{-1} and 1547 cm^{-1}). For olefinic = CH/lipid and CH_2 /lipid ratios, the areas under the olefinic = CH (3012 cm^{-1}) and the CH_2 asymmetric stretching (2925 cm^{-1}) modes were divided to the total saturated lipid (the sum of the area under the CH_2 asymmetric and symmetric stretching bands).

RESULT AND DISCUSSION

As being major components of brain tissue, any change in the structure and function of biomolecules such as lipids and proteins directly affects the proper functioning of the neural network.

In the current study, we analyzed distinct regions of brain, each of which contains various cellular and molecular components. In this complexity FT-IR spectroscopy is insufficient to provide information about specific components. However, as a result of the Conne advantage, the vibrations of functional groups in different biomolecules appear at distinct wavenumber values in an FT-IR spectrum. This enables separation of the peaks from different biomolecules to be analyzed even in weak absorption modes (Gasper et al. 2009; Leskovjan et al. 2010; Elibol-Can et al. 2011; Turker et al. 2014b). Therefore, it is possible to monitor saturated lipids, unsaturated lipids, cholesterol ester, triglycerides, proteins, nucleic acids and

carbohydrates. The present study was conducted to comparatively analyze whole brain, right and left hemispheres, hippocampus and cerebellum sections of Wistar rats. To achieve this, we monitored the variations in the frequencies, bandwidths and peak areas of some vibrational modes of biomolecules as previously performed in other reports (Cakmak et al. 2011; Ozek et al. 2014; Turker-Kaya et al. 2016).

According to Beer–Lambert law, the intensity and area of an absorption band in an FT-IR spectrum offers relative information on the content of corresponding functional groups within complex tissue systems (Berger et al. 2010; Leskovjan et al. 2010). This has been previously confirmed by biochemical assays for LPPs (Severcan et al. 2005; Leskovjan et al. 2012; Turker et al. 2014a), proteins (Bozkurt et al. 2012) and lipids (Derenne et al. 2012). By utilizing this, in the current study, we evaluated area ratios of some modes to predict the changes in the content of these molecules without need of biochemical assays.

An FT-IR spectrum obtained from rat brain tissue sample is shown in Figure 1. As demonstrated in the figure, there are many bands of at different wavenumbers in the spectrum of the brain tissue, so the spectrum is quite complex. Table 1 illustrates assignment of each infrared band based on the literature (Wetzel et al., 1999; Toyran et al., 2004; Demir et al., 2015).

In order to show the spectral differences among the groups in more detail, spectra were divided into two separate regions, 3050-2800 cm^{-1} and 1800-900 cm^{-1} . Figure 2 and 3 illustrate average spectra of WB, LB, RB, CR, and HP groups in 3050-2800 cm^{-1} and 1800-900 cm^{-1} region, respectively. Table 2 represents numerical results of spectral analysis of each group.

Figure 1. An average FT-IR spectrum obtained from rat brain tissue sample in 4000-900 cm^{-1} wavenumber range.

The myelin sheath, a phospholipid layer surrounding the axons of neurons, has a very high lipid content due to its multilayer structure and a greater lipid-protein ratio than most cellular compartments. Thus, the lipid bands observed in the brain tissue may originate from the myelin sheaths. For this reason, it is important to define such differences in lipid molecules that may cause deterioration in signal transmission in the brain (Palus et al., 2017).

Table 1. General band assignments of average FT-IR spectrum of rat brain based on the literature

No	Frequency (cm ⁻¹)	Definition of the spectral assignments
1	3012	Olefinic = CH stretching: unsaturated lipid
2	2956	CH ₃ asymmetric stretching: mainly lipid with little contribution from protein, carbohydrate and nucleic acid
3	2925	CH ₂ asymmetric stretching: mainly lipids with little contribution from protein, carbohydrate and nucleic acid
4	2852	CH ₂ symmetric stretching: mainly lipid with the little contribution from protein, carbohydrate and nucleic acid
5	1740	Saturated ester C=O stretch: phospholipid, cholesterol esters triglyceride
6	1645	Amide I (protein C=O stretch): protein
7	1547	Amide II (C=N and N-H stretching): protein
8	1400	COO ⁻ symmetric stretching: fatty acid
9	1306	Amide III: protein
10	1236	PO ₂ ⁻ asymmetric stretching: phospholipid and nucleic acid
11	1080	PO ₂ ⁻ symmetric stretching: phospholipid and nucleic acid
12	970	C ⁺ -N-C stretching: nucleic acid, ribose phosphate main chain vibrations of RNA

Similarly, brain tissue depends on oxidative pathway to utilize fuels, and has high content of unsaturated lipids when compared with other organs. This also brings about high level of mitochondria where reactive oxygen species are produced (Adam-Vizi et al., 2005). These molecules readily attack lipids and lipid peroxidation occurs, and LPPs are released into extra and intracellular site of cell (Cakmak et al. 2011; Turker et al. 2014a). Therefore, the detection of LPPs may provide information about not only possible pathogenesis of any condition but also antioxidant capacity of an agent in tissues, also shown by earlier studies (Battisti et al. 2008; Ramana et al. 2014). For this reason, in the current study, we specifically compared brain regions in terms of content of unsaturated lipids and presence of LPPs. In Figure 1, the olefinic band at 3012 cm⁻¹ originates from the C-H stretching mode of the HC = CH groups. It gives information about the degree of unsaturation of the acyl chains, particularly in the membrane lipids and lipid peroxidation (Turker-Kaya et al., 2016). Normally, when a decrease in unsaturated lipids occurs, a lower value in both olefinic mode area and olefinic/lipid ratio is expected. However, when reduced amount of unsaturated lipids is caused by lipid peroxidation, presence of LPPs results in an increase in olefinic mode area and olefinic/lipid ratio is observed as reported earlier (Turker et al. 2014a). This may be due to the loss of unsaturation being compensated by the presence of = CH groups in LPPs such as lipid aldehydes and alkyl radicals (Liu et al., 2002; Turker-Kaya et al., 2016). The ratio values of olefinic/lipid for all groups are given in Table 2. As seen from the table, when compared to the others, the lowest value was obtained in CR. The obtained finding may be resulted from low level of unsaturated and LPPs and high content of saturated lipids and/or both. On the other hand, while HP was same with WB, there was no difference between RH and LH. This shows that the unsaturated lipids and LPPs are accumulated least in CR in contrast to other regions of brain.

Membrane proteins such as membrane-bound enzymes, ion channels and receptors are dominantly present and function in nerve cell activity (Turker et al., 2014a). These types of proteins are classified as integral membrane proteins and peripheral membrane proteins.

Integral membrane proteins are in contact with with fatty acyl chains of membrane lipids whereas peripheral membrane proteins are predominantly bound to lipid head groups (Boggs et al., 1987; Brasseur et al., 1997; Turker et al., 2014b). Due to these bilateral interactions between membrane lipids and proteins, physical properties of lipids and proteins mutually affect their activity (Sandermann et al., 1978; McElhaney et al., 1982; Yeagle et al., 1992). To evaluate distinct brain regions in terms of physical state of membrane lipids, which determine their packing within bilayer, we monitored the frequency changes of the CH₂ asymmetric (2925 cm⁻¹), the CH₂ symmetric (2852 cm⁻¹), the C=O (1740 cm⁻¹), the PO₂⁻ asymmetric (1236 cm⁻¹) stretching bands. The CH₂ asymmetric and CH₂ symmetric stretching bands are mainly due to acyl chains of membrane lipids (saturated lipids) (Turker et al., 2014a; Turker et al., 2014b).

Figure 2. Representative FT-IR spectra of WB, RH, LF, CR, HP groups in the region between 3050–2800 cm⁻¹.

And, the monitoring of frequency shifting of these bands give information about order and disorder state of membrane (Turker et al., 2014b). Changes in the frequency values of such modes is related with the alterations in amount of gauche or trans conformers in the acyl chains. This may further cause the membrane to be loose or tightly packed (Senak et al., 1993, Akkas et al., 2007; Turker et al., 2014a). Evaluation of the frequency values of the CH₂ asymmetric and CH₂ symmetric band revealed no significant differences among all groups (Table 2). This may mean that there is no prominent variation in membrane order and acyl chain packing parameters of the regions in compared to WB. On the other hand, in Figure 3,

the C=O stretching band at 1739 cm^{-1} is a band that attributes to triglycerides, cholesterol, and carbonyl groups of phospholipids (Severcan et al., 2005; Turker et al., 2014a). The PO_2^- asymmetric stretching band at 1229 cm^{-1} is bound to the phosphodiester backbone of phospholipids and cellular nucleic acids (Cakmak et al., 2006). The shifts in the C=O and the PO_2^- asymmetric modes to lower wavenumbers suggest an increase in the hydration state of the glycerol backbone near the hydrophilic part and polar head group of the membrane lipids. The hydrogen bonding might be between water molecules and the oxygen molecules of both carbonyl and phosphate groups of phospholipids or hydrophilic protein residues (Akkas et al., 2007). As seen in Table 2, the C=O frequency value shifted to higher values in both RH and LH but lower values HP and CR when compared to WB. On the other hand, any significant shifting in PO_2^- asymmetric frequency value was not observed among the groups. These corresponding findings may mean that physical state of glycerol backbone near the hydrophilic part of membrane lipids show variations depending on specific brain regions. Nevertheless, state of acyl chain and phosphate groups of membrane lipids do not differ in distinct part of investigated regions of brain. Such parameter also reflects packing parameter of acyl chains of membranes.

Table 2. The values are the mean $\pm$ standard deviation for each sample

	WB (n = 7)	RH (n = 6)	LH (n = 6)	HP (n = 6)	CR (n = 6)
Frequency					
CH ₂ asymmetric	2924.42 $\pm$	2923.88 $\pm$	2924.49 $\pm$	2923.32 $\pm$	2923.22 $\pm$

	0.99 $\pm$ 0.07	0.85 $\pm$ 0.014	21.47 $\pm$ 0.11	1.01 $\pm$ 0.09	
			8.14 $\pm$ 0.04		20.52 $\pm$ 0.04
	22.85 $\pm$ 0.16	20.67 $\pm$ 0.14		21.41 $\pm$ 0.14	9.71 $\pm$ 0.008
	9.82 $\pm$ 0.06	8.14 $\pm$ 0.03		9.71 $\pm$ 0.005	

Changes in the fluidity of the cell membrane can be determined by investigating the bandwidth values of the CH₂ asymmetric stretching mode (Severcan et al., 2010, Turker-Kaya et al., 2016). The bandwidth value of this band gives information about the dynamics of the system (Turker et al., 2014b). As illustrated in Table 2, the highest value of CH₂ asymmetric bandwidth values is observed in WB. The obtained lower values in other regions may imply reduced lipid fluidity (Turker-Kaya et al., 2016). Here, it should be emphasized that this result related with fluidity is about all membraneous structures in brain rather than specific subcellular membranes of organelles. In other words, our samples contain all membrane compartments in addition to cell membrane. For that reason, the obtained outcome reflects cumulative fluidity parameter. Decrease in fluidity might have resulted from

variations in unsaturated lipids, which in turn causing the formation of kinks and force the molecules further apart and allow for more movement. Thus, a lowered membrane fluidity found in the current study can be another indication of functional changes of membrane proteins.

CH₂/lipid ratio was calculated to determine the alterations in the membrane phospholipids chain length (Cakmak et al., 2016). When the ratio of CH₂/lipid is examined in Table 2, it is seen that this value is similar in the HP and RH, while the highest value is in the CR and the lowest value is in the WB.

The bands at 1645 cm⁻¹ and 1540 cm⁻¹ in Figure 3 correspond to amide I and amide II bands of proteins, respectively. Amide I is mainly caused by C=O stretching of proteins while amide II is reassigned to N-H and C-N stretching (Cakmak et al., 2006; Turker et al., 2014a). They are used to determine protein structure or conformation and functional differences (Yan et al., 2014). When the 1650 cm⁻¹ amide I band frequency values are examined in Table 2, the highest value was observed in WB, then the HP value came. The RH and CR tissues were similar. The lowest frequency value was observed in the LH. This means that there are structural variations in protein among brain regions.

Figure 3. Representative FT-IR spectra of WB, RH, LF, C, H groups in the region between 1800–900 cm⁻¹.

When membrane lipids and proteins are thought to be in contact with each other, any change in the ratio of these molecules can alter membrane thickness and affect lipid regulation and fluidity (Awayda et al., 2004; Cakmak et al., 2011; Turker et al., 2014a). In this context, we calculated the lipid/protein ratio. As shown in Table 2, this ratio is similar in

WB and HP tissues and the highest value is in the LH tissue. The lowest values belong to the right RH and CR tissues.

As a result, when all these differences are taken into account, changes in fatty acids, protein conformation, and ratios in different brain tissues support neurochemical asymmetry studies between brain regions. At the same time, the parameters of the right-left hemisphere, cerebellum, and hippocampus tissues may be related to the functions of the brain parts, which are different from whole brain tissue parameters. However, the relationship between neurochemical changes and functions is not yet known.

ABSTRACT

The transmission of the energy to the higher levels is through the food chains, starting from the main source plants. There is a balance between all the livings in the ecosystem in which the plants are the first ring of this chain. Environmental mutagens and other related substances threaten humans and all other living organisms in an ecosystem. Plants are exposed to various types of environmental agents such as agricultural pesticides and plant growth regulators, or accidentally present in polluted air, soil or water. While pesticides used against harmful effects of agricultural production affect the target organisms, they can affect the non-target organisms through wrong and especially excessive applications. The adverse effects of toxic agents that accumulate in aquatic and terrestrial crops in an ecosystem and accumulate there as a bioindicator in plants should be identified?. Plant biotests are very important methods for evaluating the genotoxic contamination in the environment. For quick determination and measurement of the genotoxicity for these stress factors various molecular and biochemical tests are required. Single cell gel electrophoresis is also known as Comet assay that is used to investigate the cell response to several biotic and abiotic genotoxic agents leading to oxidative DNA damage. The Comet assay is used as a useful tool in assessing the potential of plants as source of information on the genotoxic impact of dangerous pollutants and sensitive sensors in ecosystems. This technique is based on the quantification of denatured DNA fragments migrating out of the cell nucleus during

electrophoresis. Current review aims to give information about Comet assay and its applications as a valuable tool for monitoring DNA damage in different plant systems. The single cell gel electrophoresis studies were performed by our group to determine the genotoxic effects of different concentrations of pesticides, heavy metals and different plant growth regulators used in tissue culture applications in tobacco as model organisms, cereals (barley and wheat) and sunflower.

Keywords: COMET, biomonitoring, genotoxic effect, plant

INTRODUCTION

As it is known, plants are the main source in energy transmitting to higher levels in the food chain. The first ring of this chain are plants, the next rings are herbivores and carnivorous containing animals and humans. There is a balance between all living things in an ecosystem. The change that occurs at any level causes fluctuations in the different stages, causing the distortion of the existing balance. Today, the balance in different ecosystems is affected negatively by genotoxic agents in particular. Environmental mutagens and other related substances threaten humans and all other living things in an ecosystem. For example, pesticides are one of the chemicals that all living beings in the nature are exposed to. Pesticides are harmful to other living organisms as well as the target they are applied to, but they are the most effective fighting methods used to prevent the waste of agricultural products. Therefore, with proper use, the effects on other living things outside the target organisms should be tried to be minimized.

The adverse effects of toxic agents that accumulate in end-of-year aquatic and terrestrial ecosystems and accumulate in fisheries and plants that are studied as bioindicators should be identified. It is also a necessity for human health and well-being.

Genotoxic damage has negative effects on the important physiological conditions required for healthy life such as rejuvenation of living things, genetic characteristics and population dynamics. Various methods are currently being used to determine whether the DNA molecule is at risk for mutagenic effects and genotoxicity. One of the methods used to examine the genotoxic risk ratios is the Comet test, where direct DNA damage is measured. Single cell gel electrophoresis (SCGE) or so-called "Comet assay"; is a more sensitive and reliable method that results in shorter time than conventional cytogenetic methods used in measuring genotoxic risk ratios (Gichner et al., 2003; Lin et al., 2007). The Comet method has also the advantages such as allowing direct measurement at the DNA level and detecting genetic damage in a short time and directly. Use of this technique also extends the utility of plants in basic and applied studies in environmental mutagenesis.

The DNA breaks which migrate out of the nuclei embedded in a thin agarose layer can be measured by comet assay (Menke et al., 2001). The preparation of uniform and stationary gels in the slides is crucial to ensure that the cells embedded in the gel can be retained intact until the end of the experiment phase and to remove the factors that could affect the background appearance of the samples and in order to increase the gel fixation, roped lamellae are used (Tatli et al., 2008). The slides are placed in the electrophoresis tank containing the buffer solution and allowed to stand for a while in order to unwinding the DNA. If the unwinding and electrophoresis steps are carried out in an alkaline pH

environment, the breaks of the double and single strand in the DNA can be determined. If both the unwinding and the electrophoresis are more than carried out in pH 13, the base damage in the crosslinks as well as the breaks in the double and single strand can be determined. It is very important to keep the temperature constant during electrophoresis in order to avoid the differences that may occur between samples. The slides are washed at room temperature with 0,4 M Tris-HCl (pH 7,5) to neutralize the resulting alkali medium following electrophoresis and to provide a clear image under the microscope (Gichner et al., 2008b; Rank et al., 2009).

Detection of DNA single strand breaks in cells was first described by Rydberg and Johanson (1978). Cells were embedded with agarose on a microscope slide and cell lysed under lightly alkaline conditions to allow partial dissolution of DNA. The cells were stained with acridine orange after neutralization and photometrically analyzed. The proportion of double-stranded DNA to single-stranded DNA, the proportion of green fluorescence to red fluorescence, and the extent of DNA damage were determined. Ostling and Johanson (1984), have increased the sensitivity in the detection of DNA damage in cells by improving the Microgel Electrophoresis techniques. The technique proposed by Ostling and Johanson is based on spiral breaks in DNA and the mechanism by which this structure can be pulled out and attenuated by electrophoresis. Singh et al. (1988) have developed a method that allows detection of DNA damage under alkaline conditions by modifying the microgel electrophoresis technique. In this technique, electrophoresis is carried out at high pH.

Table 1. Types of DNA damage that can be detected by Comet assay at different pH

N/N (pH: 7-8)	A/N pH: 10-12	A/A pH > 13
Double strand breaks	Double strand breaks	Double strand breaks
Cross links	Single strand breaks	Single strand breaks
	Excision repair sites	Excision repair sites
	Cross links	Cross links
		Alkali injuries

Versions such as N/N (Neutral Dissolution/Neutral Electrophoresis), A/N (Alkaline Dissolution/Neutral Electrophoresis) and A/A (Alkaline Dissolution/Alkaline Electrophoresis, pH 13) developed for different pHs (Table 1) are also used in the Comet assays (Gichner and Plewa, 1998; Lin et al., 2007).

After the neutralization step, the slides are stained and analyzed within a maximum of 6 hours. If analysis can not be done immediately, the preparations are kept in cold water for 10-15 minutes, then dehydrated in 100% ethanol and left to dry. The slides can be stored for a few months under appropriate conditions (Kocyigit et al., 2005, Gichner et al., 2008 a, b).

The comet formation of nuclei followed by electrophoresis enables quantification of DNA in comet tails after staining with an appropriate fluorochrome such as propidium iodide or ethidium bromide (Olive and Banath, 2006). Despite the use of sensitive but quite expensive dyes such as YOYO-1 (benzoxazolium-4-quinolinone oxazole yellow homodimer), DAPI (4,6-diamidino-2-phenylindole) in the detection of lower levels of DNA damage, it is reported that the efficiency of the cheaper etidium bromide was not different from other dyes mentioned (Gichner et al. 2006).

Figure 1. General illustration of the Comet assay. (A, B) Isolation of nuclei from plant leaf tissue, (C) The mix of isolated nuclei and LMP agarose transfer onto the slides, (D) Unwinding of the slides in fresh alkaline or neutral electrophoresis buffer, (E) Electrophoresis of the slides in the alkaline or neutral buffer, (F) Neutralize the slides, (G) Stain the slides with a DNA binding dye and view under fluorescence microscope, (H) Analyse the results (Akan, 2012).

Following staining, migration of DNA from the nucleus is observed in damaged cells. Each damaged cell; a brilliant fluorescence head and length and fluorescence intensity has a comet image consisting of a tail connected to the number of DNA strand breaks in the cell. Undamaged cells appear as untailed, undisturbed nuclei. DNA images emerging at varying degrees of damage from circular to comet-like form are examined under a fluorescent microscope.

Utilizing the feature that the amount of DNA in a particular region is directly proportional to the fluorescence intensity in that region, and in parallel with the progress in digital imaging systems and analysis software programs, more accurate quantification methods have been developed. Image analysis systems can measure various comet parameters such as head length of damaged cells, percentage of DNA in head and tail, tail length and tail moment (Tice ve ark., 2000; Hartmann ve ark., 2003).

According to its head and tail shape of comet, the migration of DNA could be classified from 0 (no tail) to 4 (almost all DNA in tail) by visually (Kobayashi et al., 1995; Gichner et al., 2003; Kocyigit et al., 2005).

The use of Comet test with different methods affects the results. For instance, electrophoresis conditions (duration, applied voltage), lysis solution content (salt concentration and pH) and duration of application affect the sensitivity of the method. For this reason, optimizing the technique in comet labs is an important step (Hartmann et al., 2003).

COMET ASSAY IN PLANTS

Comet is an effective tool that can be applied easily to fungi, algae, plants, sea creatures, insects, vertebrate animals and humans, and to give information on environmental health (Gichner and Plewa 1998, Angelis et al., 2000; Menke et al., 2001; Dhawan et al., 2009). Although almost all plants are available for the Comet test, they are potatoes (*Solanum tuberosum*), tobacco (*Nicotiana tabacum*), soya bean (*Vicia faba*), onion (*Allium cepa*) and *Arabidopsis thaliana* in terms of ease of cultivation and cell isolation (Gichner et al., 2006; Mancini et al., 2006; Lin et al., 2008). Gichner and Plewa (1998) found that after exposure to *N. tabacum* plants with 1-8 mM Ethyl Methane Sulphonate (EMS), the highest amount of DNA damage was found in the plants exposed to the highest EMS concentration. Menke et al. (2000) investigated that the N-methyl-N-nitroso Urea (MNU) was genotoxic effective agent in *V. faba* plants in comparison with three different comet technique protocols (neutral/neutral, alkaline/neutral, alkali/alkaline). Gichner et al. (2008) conducted that comet analysis under alkaline conditions to determine the increase in induced DNA damage in *S. tuberosum* L. plant treated with EMS, Cd²⁺ and γ -rays, showed that the best dose-response curve was detected with the alkaline Comet technique.

SCGE, in combination with detection of Reactive Oxygen Species (ROS) and expression analysis of both DNA repair and antioxidant genes, can be used for the plant genotypes (Ventura et al., 2013). The accumulation of reactive oxygen species (ROS) are damage the cellular components such as DNA, proteins and lipids (Lopez et al., 2006).

The overproduction of ROS induced by some heavy metals can lead to the DNA damage in plants, animals and microorganisms living in aerobic conditions (Gichner, 2003; Mittler, 2002; Mancini et al., 2005), are the early responses of plant to heavy metals (Mittler, 2002; Hartley-Whitaker et al., 2001). Lin et al. (2007) reported that the enhancement in DNA damages was correlated to oxidative stress induced by Cd in leaves of *Vicia faba*, indicating that ROS accumulation in tissues caused subsequently DNA damage.

Comet assay has been used in different studies by use of plants particularly in environmental risk assessment (Table 2). Despite the fact that almost all plants are available for comet analysis, studies on *S. tuberosum*, *N. tabacum*, *V. faba*, *A. cepa* and *A. thaliana* have been found more widely in the literature (Gichner et al. 2006; Mancini et al., 2006; Lin et al., 2008).

Programmed Cell Death (PCD) is genetically controlled death and mediated by specific proteases and nucleases. During PCD cells are executed in a biological process and characterized by cell shrinkage, vacuolization, nucleus deformation and DNA fragmentation. In detailed studies of PCD DNA fragmentation is accepted as the most apparent indicator of PCD. DNA fragmentation in dying cells is visualized/measured by several analyses such as DAPI staining, TUNEL reaction, flow cytometry, gel electrophoresis and Comet assay (Vardar et al., 2011; 2012; 2015; 2016). Although the DNA damage can be visualized and measured by Comet assay, the whole of comets may not be considered as PCD. It is the fact that the damaged cells will subsequently be undergone irreversible PCD. Considering the fact that DNA damage might be repairable, the Comet tail can be no longer seen under proper conditions. Besides damaged cells die and disappear, but in comet assay the damaged cells are still present and detectable. Moreover, DNA fragmentation during PCD is characterized by DNA cleavage into 180-200 bp length oligonucleosomal fragments. During

electrophoresis in Comet assay such small parts of DNA will probably disappear (Collins et al., 1995; Collins, 2004). To overcome these difficulties Singh (2000) described a visualization method of dying cells. In this technique cells are embedded in the agarose and lysed. But the researcher precipitated the DNA, instead of electrophoresis. The dying cells distinguished by halo of granular DNA and a hazy outer boundary (Singh, 2000). The inverse relationship between the application time and the DNA damage can be explained by the partition of the enzymatic processes in the formation of DNA damage of pollutants causing toxicity (Ali and Kumar, 2008). Akan (2012) reported that CPF application in barley plant demonstrated that there was an inverse relationship between DNA damage and application time. Long-term studies are required to examine the repair of DNA damage, protective mechanisms and enzymatic processes is suggested in this study.

Table 2. Selected Comet assay studies in plant toxicology (Santos et al., 2015)

Stress	Species	Tissue	Comet type
Radiation			
Light	<i>A. thaliana</i>	Leaves	A/ApH > 13
UV	<i>A. thaliana</i>	Leaves	A/ApH > 13
X-ray	<i>A. thaliana</i>	Leaves	A/ApH > 13
Metals			
Monovalent	<i>V. faba</i>	Roots, leaves	A/ApH > 13
Divalent	<i>A. cepa</i>	Roots	A/ApH > 13
Trivalent	<i>A. thaliana</i>	Roots	N/N pH 8.4
Oxoanions	<i>A. cepa</i>	Roots	A/ApH > 13
Nanocompounds			
MWCNT	<i>A. cepa</i>	Roots	A/ApH > 13

Metal oxideNPs	<i>A. cepa</i>	Roots	A/A pH > 12.3
Quantum dots	<i>M. sativa</i>	Cell suspension	A/ApH > 13
Organic pollutants			
Dyes	<i>A. cepa</i>	Roots	A/ApH > 13
Pesticides	<i>A. cepa</i>	Roots	A/ApH > 13
Polyhalogenated	<i>A. cepa</i>	Roots	A/ApH > 13
Phytocompounds			
	<i>A. cepa</i>	Roots	A/ApH > 13
Others			
Osmostressors	<i>A. thaliana</i>	Seedlings	N/N pH 8
Control mutagens			
	<i>A. cepa</i>	Roots, leaves	A/ApH > 13

Agronomic crops as well as other plants are deliberately exposed to pesticides and other chemicals applied in modern agriculture. These pollutants are hazardous for the plants. Basudine and antracol pesticides, destroys crop and livestock. In our study, genotoxic potential of Basudine and Antracol were determined using Single Cell Gel Electrophoresis (SCGE) in tobacco (*Nicotiana tabacum* L.) which is model plant and it is suitable for genetic and physiological studies. The Comet assay has been widely used in the fields of genetic toxicology and environmental biomonitoring by evaluating DNA strand breaks.

Pesticide applications can cause damage due to many factors. These factors include the form of dose (how much is applied), duration (how long it is applied), and how contact occurs. In addition, the presence of any other chemicals exposed, the age and other characteristics of the organism must be taken into consideration.

In the study conducted by Aydın et al. (unpublished data), possible genotoxic effects of Basudin (fungicide - active ingredient: Diazinon) and Antrakol (insecticide - active ingredient: Probinex) pesticides on model organism tobacco plant (*Nicotiana tabacum* L.) were evaluated by single cell gel electrophoresis. Diazinon can reduce its fixation ability by nitrogenous soil organisms, an important plant nutrient and nitrogen fixation is a process that transforms atmospheric nitrogen into a form that can be used by plants. Diazinon applied to the soil is absorbed by plant roots and can be translocated in plants (Kamrin, M. A., 1997). Their half-life ranges from 2 to 14 days. Low temperature and high fat content increase the durability of diazinon in plants (Kamrin, M. A., 1997). Diazinon also causes genetic damage in plants. Diazinon application with onion (Grover et al., 1987) and barley (Kour and Grover, 1985a, Grover et al., 1987) resulted in abnormal chromosomal occurrences. In addition, seeds obtained from diazinon-treated plants contain mutations that reduce the proportion of chlorophyll in cells following germination (Grover et al., 1987). Diazinon applications to barley seeds or seedlings cause abnormal chromosomes to form in pollen cells (Kour and Grover, 1985b). Antrakol is used to destroy fungi causing damage to various vegetables and fruits (tomatoes, potatoes, onions, grapes, melons, etc.).

In this study, Basudin and Antrakol pesticides are used extensively controlling of pests on park and garden especially in İstanbul, Turkey. The genotoxic effects of these pesticides are not completely understood and the Comet assay was used for detecting DNA damage by these pesticides exposed to the model organisms, tobacco (*N. tabacum*).

Thus, the aim of this study was to evaluate the genotoxic effects of acute exposures (24, 48, 72 and 96h) to 0.925, 1.85, 2.775 mg/ml of Basudin and 0.5, 1, 1.5 mg/ml of Antrakol on two-week-old tobacco seedling. Tobacco plants germinated in MS (Murashige and Skoog, 1962) medium and nucleus isolated from their leaves. Leaf samples from non pesticide treated tobacco seedlings grown on MS medium were used as negative controls, and leaf samples from seedlings treated with distilled water containing 0.1% H₂O₂ (during 24 hours) were used as positive controls. Leaf tissues were disrupted with sharp razors adding cold 0.4 M Tris-HCl buffer (pH7.5). The tissues were gently sliced and isolated for collection of nuclei in the buffer. The mixture was centrifuged to remove the debris. All steps were performed in dim light and ice to prevent induction of DNA damage. Nuclei suspension was mixed with the liquid Low Melting Agarose (LMA) (1:1) by gently pipetting and as soon as agarose/nuclei mixture were spread on the slide that previously coated with High Melting Agarose (HMA). The slides were incubated in electrophoresis buffer to facilitate DNA unwinding. Thereafter, the slides were placed on horizontal electrophoresis tank filled with fresh, cold electrophoresis buffer kept cold using ice followed by performing electrophoresis. After neutralization each slide was stained with ethidium bromide and kept at 4°C until analysis. These slides observed under an epifluorescence microscope (BX51TF, Olympus) equipped with a CCD camera (Canon A640) and fifty cells per slide were analyzed with the Comet image analysis system (BAB BS200ProP). For each sample, 50 random cells were scored. The % tail DNA and olive tail momentum parameters were calculated as a measure of DNA damage. % Tail DNA values were shown as the percentage of DNA in comet tail. Olive tail moment values were shown as multiplication of % tail DNA and difference between center of

gravity of DNA in the tail and center of gravity of the head DNA. The results showed that Basudin and Antrocol produce genotoxic damage in leaf nucleus of *N. tabacum*. The comet scores obtained for tobacco after all time points of exposure to Basudin and Antrocol were significantly higher than the respective negative control ($P < 0.001$). In conclusion the result of this work showed that Basudin and Antrocol induced genotoxic effects on the plant species *N. tabacum*. The genotoxic effects were observed in all Basudine and Antracol concentrations and exposure times in tobacco (Table 3, Figure 2 and Figure 3).

It has been determined that diazinon inhibits the activity of an enzyme in soil microorganisms that “plays an important role” in the nitrogen cycle (Frankenberger and Tabatabai, 1991). Diazinon also reduces the amount of nitrogen compounds in the soil (Ingham and Coleman, 1984).

Comet analysis of the findings, as well as the determination of pesticide spraying and harvesting time of use to determine appropriate doses contributed to the work.

Figure 2. DNA migration pattern from *Nicotiana tabacum* L., exposed to different concentrations of Basudin with different exposure times. Objective: 20X. Dye: EtBr (Unpublished data).

In vitro culture factors could apparently lead to oxidative stress and genotoxicity. The plants produce oxine and cytokine in their own tissues. These hormones can reach high doses in plants by supplementing these plant growth regulators from outside in plant tissue culture

studies. The production of auxin and cytokine may be distinct in plants for different gene sources. In recent years, in vitro techniques have been extensively used for abiotic stress (Şen, 2012) and genotoxic effects.

Table 3. DNA damage at different concentrations and exposure times of Basudin and Antracol (%DNA tail and Olive tail moment)

Pesticide	Dose	Time (hour)	%DNA tail	Olive tail moment
Basudin	(-) control		26	0.26
	(+) control	18	36	0.26
	0.925 mg/ml	24	29	0.20
		48	28	0.21
		72	38	0.29
		96	36	0.34
	1.85 mg/ml	24	33	0.20

		48	33	0.22
		72	28	0.12
		96	25	0.11

In another study conducted by our group, it was evaluated the changes on genotoxicity derived from androgenic callus tissues with the effect of plant growth regulators, genotypes and pretreatments in sunflower by Comet assay. The method of Çavaş and Könen (2007) was used by some modifications in this study. Obtaining callus tissues were used as material to detect the DNA damage levels by Comet assay. Leaf of sunflower grown in MS medium for two weeks was used as a negative control and leaf of sunflower that grown in MS medium supplemented with 150 μM AlCl_3 for two weeks was used as positive control. Callus and leaf tissues were disrupted with sharp razors adding cold 0.4 M Tris- HCl buffer (pH=7.5). The slides were analyzed under a fluorescent microscope at 20X magnification. For each sample, 50 random cells were scored. Comet parameters were measured and analyzed using KAMERAM software. The % tail DNA and olive tail momentum parameters were calculated as a measure of DNA damage. % Tail DNA values were shown as the percentage of DNA in comet tail. Olive tail moment values were shown as multiplication of % tail DNA and difference between center of gravity of DNA in the tail and center of gravity of the head

DNA. Overall results we obtained indicated that genotype, medium type and pretreatment factors especially plant growth regulators could apparently lead to genotoxicity and medium type is the most effective parameter for genotoxic effect on sunflower (unpublished data).

Figure 3. DNA migration pattern from *Nicotiana tabacum* L., exposed to different concentrations of Antracol with different exposure times. Objective: 20X. Dye: EtBr (Unpublished data).

In conclusion; Comet assay is a fast, easy and reliable method to evaluate DNA damage on living organisms and in vitro and in vivo studies with different concentration and exposure periods induced by various types of genotoxic agents. Comet assay also can be employed in specific tissues or cells such as roots and leaves. These characteristics of the assay make it to be used in evaluating various types of environmental toxic conditions. Although Comet assay is most used the evaluating the acute effects of genotoxic agents, it can be also used to reveal DNA repair in plant physiology, as this technique may help elucidating pathways involved in plant development, cell cycle/programmed cell death, or even plant disease resistance. Long-term genotoxicity studies can be an important approach to gaining insight into the ability of organisms to repair DNA and other protective mechanisms.

Kocaeli University, Kocaeli, Turkey

²Department of Nursing, Kırklareli University, Kırklareli, Turkey

ABSTRACT

This study was designed as a descriptive study, to analyze the sensitivities of the nurses working in the surgical services of a state hospital on patient rights. The universe of the study consisted of 61 nurses working in the surgical services of a state hospital while the sample of the study consisted of 54 nurses volunteered to participate in the study between July 26 and October 1, 2010. The data of the study were collected with the personal information form and the Belief of Patient Rights Form (BPRF). In the statistical analysis of the results, frequency, percentage, mean, standard deviation, Mann Whitney U and Kruskal Wallis-H tests were used. The mean total score of BFRF of the nurses was 32.85 ± 6.66 ; the differences between the nurses' scores on the BFRF and the subscales of privacy and private life and application were significant according to their ages ($p < 0.05$); the difference between the nurses' scores on the consent subscale was significant according to their education levels ($p < 0.05$). It was determined that the surgical nurses who were 29 years old or younger, university graduates, had less than 5 years' study period and took courses on patient rights, had high sensitivity to patients' rights. It can be recommended to add related courses in the curriculum during the education and to plan training programs by considering age group, the level of education, working time and the status of taking related courses, for improving nurses' sensitivity to patient rights.

Keywords: surgical nursing, surgical service, hospital, awareness, patients' rights

INTRODUCTION

Patient rights are defined as the rules of conduct between people who benefit from health services and the health institutions and personnel who provide them (Teke et al., 2007; Ozakar Akca et al., 2015). As these rights relate to particular circumstances in human life, it is also defined as third generation human rights and covers the application of human rights and values in health services. Top priorities of patient rights include: to be respected as a human being, receive health service in a high level, get information, get confirmation for medical processes, privacy, and respect for private life, while receiving care and treatment continuity (Erbil, 2009; Ozakar Akca et al., 2015).

In recent years, advances in science and technology have made being informed about treatment and care initiatives necessary for patients (Savaskan, 2006). This change and development has led the nurse's care function to mainly focus on new roles. One of the contemporary roles of the nurse is to stand up for patient rights (Ardahan, 2003). In this context, nursing is aimed to be a discipline protecting patient rights, implementing care and treatment, ensuring the safety of the patient, advocating and implementing the right thing for the patient (Ardahan, 2003; Ozer et al., 2009; Erzincanli & Zaybak, 2015). Therefore, nurses have obtained the identity of being a health professional being a guide of the patients to know and acquire their rights. Patients who can not choose the best for themselves, often do not have knowledge of their rights therefore they need the help of a nurse who can guide them on how to obtain these rights. Nurses have more interactions with patients than other health care team members. For this reason, it is very important that nurses have enough information about the subject and can apply this knowledge in practice (Teke et al., 2007, Zaybak et al., 2012, Ozakar-Akca et al., 2015, Oztas & İyigun, 2016). The sensitivity of nurses to patient rights also positively affects the satisfaction levels of patients in the institution (Tanriverdi & Ozmen 2011; Erzincanli & Zaybak, 2015).

It is the ethical responsibility of nurses to undertake the role of patient advocacy in this period because the individuals/patients undergoing surgical intervention experience anesthesia and sedation. In surgical departments in which invasive procedures are mostly performed, it is also important to obtain the patient's informed consent, the nurse has the ethical responsibility to obtain the informed consent after understanding of the operation by the patient (Karaoz, 2000; Temiz et al., 2017). In the study of Ozer et al., (2009) which investigated the knowledge levels of patients treated in surgical clinics, it was reported that the mean knowledge scores of the patients was 11.67 ± 3.32 on a 17 point scale, 86.1% of the patients did not receive information about patient rights during hospitalization, the patients stated that the highest importance was given to the right of having a hospital attendant and while the lowest importance was given to the right of requesting information about their health status verbally and by writing in the services in which they stayed.

Within the scope of ethical principles, securing confidentiality of patients is also among the responsibilities of nurses when patients are not able to protect their own privacy due to their state of consciousness during the surgical preparation period, during the procedure, and in the postanesthesia care unit (Karaoz, 2000; Tumer et al., 2011; 2017). It was determined that most of the studies related to the subject analyzed the level of knowledge of the medical staff (Teke et al., 2007; Zincir & Kaya 2009; Kavak et al., 2014; Khalaf et al., 2014; Ozakar-Akca et al., 2015) and the patients (Ozer et al., 2012; Erzincanli & Zaybak 2015; Oztas &

İyigun 2016) about patient rights. Therefore, this study was designed and carried out in order to determine the sensitivity of the nurses working in surgical units to patient rights because of lack of the studies on the sensitivity of nurses working in surgical units about patient rights. For this purpose, three questions below were asked

- What are the knowledge levels of the surgical nurses about patient rights?
- How is the surgical nurses' sensitivity to patient rights?
- Is there any difference between personal and occupational characteristics of surgical nurses and sensitivity to patient rights?

MATERIALS AND METHODS

Universe and Sample of the Study

The study was planned as a descriptive and cross-sectional study and was carried out between July-October 2010. The universe of the study consisted of 61 nurses working in the surgical clinics of a state university. No sample selection criteria were used, 54 nurses who agreed to participate in the study were included in the study.

Data Collection

The research data were collected with the personal information form and the Belief of Patient Rights Form (BPRF). In the personal information form, the information such as age, gender, marital status, education status, duration of study, education about patient rights, meeting with the patient rights concept, having a problem related with patient rights and the presence of a unit related to patient rights in the institution where the nurse works are included.

The BPRF is a 5-point liker-type scale that consists of 6 sub-dimensions (human rights and values in health care services, informing, approval, privacy and private life and application) and 18 questions determining the views of nurses on their beliefs about patient rights. The participants in the study were asked to mark one of the following expressions: "absolutely agree", "I agree", "I slightly agree", "I disagree", "I absolutely disagree". In the evaluation of the form, 1 point was given for the answer "Absolutely Agree", 2 points was given for the answer "Agree", 3 points was given for the answer "Slightly Agree", 4 points was given for the answer "Disagree" and 5 points was given for the answer "Absolutely disagree". The lowest possible score is 18 while the highest possible score is 90. Low scores indicate high agreement on patient rights (high sensitivity), and high scores indicate low agreement on patient rights (low sensitivity).

Statistical Analysis

The data were analyzed by SPSS 20 package program. Mann Whitney U and Kruskal Wallis-H tests were used because the data did not fit normal distribution. $p < 0.05$ was considered as statistically significant.

Ethical Statement

The written permission was obtained from the Hospital Directorate. Participants were informed about the aim of the study; A verbal permission was obtained from each participant who voluntarily participated in the study. Participants were reassured about the confidentiality of their information; they were informed about the aim and scope of the study.

Limits of the Study

The study was conducted with the surgical nurses in a state hospital, this may be accepted as a limitedness of the study in terms of generalizability.

RESULTS AND DISCUSSION

The study was conducted to determine the sensitivity of surgical nurses to patient rights; the results were interpreted and discussed below. No study was found to analyze the sensitivity of surgical nurses to patient rights as a result of that some difficulties were experienced in the discussion of our findings.

It was found that 40.7% of the nurses were between the ages of 30-34, 94.4% of them were female; 72.2% of them were married; 51.9% of them had an associate's degree; 31.5% of them started to work 11-15 years before. The findings on the personal and professional characteristics of the nurses were similar to the findings of Zincir & Kaya (2009), Kavak et al., (2014).

Table 2 shows where the nurses first met with the concept of patient rights, the status for taking a training about patient rights and having a problem about patient rights and the presence of the patient rights unit at the hospital. Accordingly, it was determined that 55.6% of the participant nurses met the concept of patient rights for the first time in the hospital. The patient rights need to be known and implemented by every health care staff in order to increase the quality of the service provided in the field of health, to prevent patient rights violations both morally and legally and to increase the satisfaction level of the patients by meeting their expectations (Tanrıverdi &, Özmen 2011; Öztas &, İyigün 2016). Similarly, Ozakar-Akca et al., (2015) also found that 75.9% of nurses heard the concept of patient rights in the hospital for the first time; Teke et al., (2007) found that 64.2% of nurses met patient rights by using out of school sources. This condition suggests that nurses who are very close to the patients and who spend most of their daily working time with the patients do not learn enough information about patient rights in school education and practices.

Table 1. The frequency distribution related with the personal and professional characteristics of the nurses (n = 54)

Characteristics		n	%
Age	≤29	17	31,5
	30-34	22	40,7
	≥35	15	27,8
Gender	Female	51	94,4
	Male	3	5,6
Marital status	Married	39	72,2
	Single	15	27,8
Educational status	HS/VHS	16	29,6
	Associate Degree	28	51,9
	Bachelor	10	18,5
Working time	0-5 years	15	27,8
	6-10 years	13	24,1
	11-15 years	17	31,5
	≥16 years	9	16,6
Total		54	100,0

HS: High School; VHS: Vocational High School.

Table 2. Distribution of the nurses' knowledge on patient rights (n = 54)

Knowledge about patient rights		n	%
The place for meeting the concept of patient rights for the first time	Not meet	1	1,9
	Book, brochure	2	3,6
	TV	3	5,6
	Symposium, conference	6	11,1
	School	12	22,2
	Hospital	30	55,6
The status for getting training on patient rights	Yes	42	77,8
	No	12	22,2
The status for experiencing a problem related with patient rights	Yes	17	31,5
	No	37	68,5
The presence of the patient rights unit in the hospital	Yes	50	92,6
	No	4	7,4
Total		54	100,0

It was determined that 77.8% of the participant nurses received education on patient rights. There is a close relationship between the essential values that constitute the nursing profession (Karaoz, 2000; Acaroglu, 2014) and the values that constitute patient rights (Patient Rights Regulation 1998). For providing ethical based care, the required importance should be given to teach care philosophy and care behaviors to them during their education period. According to Karaoz (2000), Kurtz & Wang (1991), educators, researchers and managers should collaborate in order to achieve this goal. 48.7% of the nurses got education on patient rights in the study of Savaskan (2006); 55% of the nurses got education on patient rights in the study of Teke et al., (2007); 47.2% of the nurses got education on patient rights in the study of Kavak et al., (2014); 92.3% of the nurses got education on patient rights in the study of Ozakar Akca et al., (2015). The studies have shown that health staff generally have information about the application of patient rights. According to the findings of our study and other studies (Teke et al., 2007; Kavak et al., 2014), it can be stated that the majority of nurses who got education on patient rights did not constitute the majority of educated nurses;

more importance should be given to the education about patient rights before and after the education.

In the study, it was determined that 68.5% of the nurses did not encounter a problem about patient rights while 31.5% of them encountered a problem. It is known that patients undergo extreme stress and need help from someone else to cope with this stress, from hospital application to discharge. Nurses are the most important health staff that can help patients by giving explanatory information about what to do in the treatment process. In this context, the nurses fulfill their own responsibilities by protecting the rights of the patient or by helping the protection of patient rights (Teke et al., 2007, Ozakar-Akca et al., Similarly, Ozakar-Akca et al., (2015) found that 43.8% of the nurses encountered a problem about patient rights while Teke et al., (2007) found that 18.3% of them encountered a problem about patient rights. It is remarkable that nurses who have the most interaction with patients in healthcare and who have an important role in advocating patient rights, encounter problems with patient rights at the rate of 18% to 44%. Patient rights are the rights that hospital management, patients and health professionals should protect together for a healthier care environment (Karaoz, 2000; Ozer et al., 2009; Erzincanlı & Zaybak 2015). We suggest that the intensification of educational programs, including patients-patient relatives and healthcare staff, will result in a positive change in behavior for resolving the problems related to patient rights and ensuring a healthier, more satisfying care environment. The patient rights related problems being encountered by nurses in practice is a different research subject.

In this study, it was determined that 92.6% of the nurses stated that there was a patient rights unit in the hospital. The Patient Rights Unit is a unit that is responsible for the training of health staff and patients about patients 'rights (Patients' Rights Regulation 1998), which accepts applications to prevent violations related with patient rights, provides solutions to urgent problems and informs a higher unit. Contrarily, 65.2% of the nurses stated that they did not have a board protecting the patient rights in the institution while 26.6% of the nurses stated that there was no information about the presence of the institution according to the findings of Savaşkan (2007). High awareness of the nurses about the presence of the patient rights unit in the hospital is a positive result for us.

Table 3. Distribution of the scores of the nurses on the overall BRPF scale and its subscales

Subscales	n	Mean	SD	Med	Min - Max
Human rights and values in health services	54	4,33	1,39	4	3 - 7
Informing	54	4,94	1,47	5	3 - 8
Consent	54	5,89	1,7	6	3 - 9
Privacy and private life	54	4,41	1,22	4	3 - 6
Care and treatment	54	6,13	1,52	6	3 - 11
Application	54	7,15	1,95	7	3 - 12
Total	54	32,85	6,66	34	19 - 47

Med.: Median; Min.: Minimum; Max.: Maximum; SD: Standard Deviation.

When the mean scores of the nurses on the overall BRPF and all subscales of it were analyzed (Table 3), the mean score of the nurses on the subscale of human rights and values in health services was 4.33 ± 1.39 ; the mean score of the nurses on the subscale of informing was 4.94 ± 1.47 ; the mean score of the nurses on the subscale of consent was 5.89 ± 1.7 ; the

mean score of the nurses on the subscale of care and treatment was 6.13 ± 1.52 ; the mean score of the nurses on the subscale of application was 15 ± 1.95 ; the mean total score of the nurses on the BRPF scale was 32.85 ± 6.66 . The scores can be obtained from the BRPF Scale varies between 18 and 90, therefore it can be said that the mean score of the nurses on the BRPF Scale was low. This result indicates that the sensitivity of the nurses to patient rights was high and the result was at the desired level.

In Turkey, the most important regulation on patient rights is the Patient Right Regulation, it was published in the Turkish Official Gazette (No. 23420) at 1 August 1998. This ordinance is an important document that directly and perceptibly regulates patient rights in Turkey. In the Patient Rights Regulation, the rights such as “benefiting from health services, asking for information, choosing and changing the health institution, appropriate diagnosis in compliance with medical requirements, treatment, requesting respect for privacy, not being subjected to medical applications without consent, requesting confidentiality of information, refusing the treatment” (Patient Rights Regulation 1998: 23420). The result of this study related with the mean total score of the nurses on the BRPF Scale was similar to the results of Savaskan (2006); this result suggested that the nurses provided care for the essential principles that constitute patient rights.

In Table 4, there was not a statistically significant difference between the scores of the nurses on the ‘human rights and values in health services’, ‘informing’, ‘consent’, ‘care and treatment’ subscales according age groups ($p > 0.05$). There were statistically significant differences between the scores of the nurses on the ‘privacy’ and ‘private life’, application

subscales and overall scale ($p < 0.05$). In general, the nurses with the ages of 29 years or younger had lower scores on the overall BRPF and all subscales; they had higher sensitivity to patient rights. The studies comparing the sensitivity of the nurses to patient rights according to age groups, have found different results. There was no statistically significant difference between the nurses' sensitivity to patient rights according to age groups ($p > 0.05$) in the study of Savaskan (2006) and Kavak et al., (2014). In the study of Zincir & Kaya (2009), it was reported some similar which are similar to our results, the mean knowledge level of the health workers with the ages of 29 or younger was significantly higher than the others in the older age group ($p < 0.05$). In addition, Khalaf et al., (2014) analyzed the knowledge and attitudes of health care staff about patient rights. It was found that slightly more than one third of the participants (36%) knew patient rights (40.4% of the doctors, 34.2% of the nurses); it was reported that the rights of having 'a good care and management' and 'privacy and confidentiality' were the best known rights. In this study, the nurses aged 29 years or younger had higher mean scores compared to older age group. The reason is thought to be the fact that the patient rights regulation that went in effect in 1998 and after that year this regulation started to be taught as a course in pre-graduation education. Moreover, it can be suggested that the nurses in the young age group are more likely to adopt these rights by considering the fact that the significant differences were found for the subscales of 'privacy and private life' and application'.

There was no statistically significantly difference but the scores of the nurses that with a bachelor's degree were lower on the overall BRPF and it's subscales as 'human rights and values in health services', 'informing', 'privacy and private life', 'care and treatment', 'application' subscales compared to the nurses with an associate's degree ($p > 0.05$). A statistically significant difference was found between the scores of the nurses on the consent subscale according to their educational status ($p < 0.05$, Table 5). It was observed that the mean score of the nurses having a bachelor degree on the 'consent' subscale was significantly lower compared to the nurses having an associate's degree. The nurses with a bachelor degree were generally more sensitive to patient rights. It is a legal and ethical obligation to obtain verbal and written consent from the patient or his/her relatives prior to the initiation of any surgical procedure to be applied to the patient (the Patient Rights Regulation 1998). In the study of Kavak et al., (2014), there was a statistically significant difference between the scores of the nurses on the consent subscale according to their education status ($p < 0.05$); it was found that the nurses who graduated from a health vocational high school had significantly higher knowledge level on patient consent. In the study of Zincir & Kaya (2009), there was a significant correlation between the nurses' educational status and their knowledge scores ($p < 0.05$); it was stated that the nurses having a bachelor or postgraduate degree known patient rights better than the nurses having a high school diploma and an associate's degree. Although it was determined that there were a study (Zincir & Kaya, 2009) having similar results and a study having different results (Kavak et al., 2014), the results showed that the nurses with a bachelor's degree had higher sensitivity to patient rights. In addition, the sensitivity of the nurses having a bachelor degree to patients' right of 'approval' was higher so we suggest that the nurses having a bachelor degree adopt and take care this right more.

There was no statistically significant difference between the mean scores of the nurses on the overall BRPF Scale and its all subscales according to their working time, the nurses having < 5 working years had a lower mean overall BRPF score; their sensitivity to patient rights was higher. Our results are similar to the results of the study of Savaskan (2006) in which there was no significant difference between the nurses' beliefs about patient rights according to their working years. Savaskan, (2006) stated that the nurses having < 5 working years had a lower mean overall BRPF score. In conclusion, it can be suggested that more place has been given to patient right in the curricula in the recent time because patient rights has been a topical issue, this condition may increase nurses' sensitivity to patient rights; increasing working years cause a decrease in the willingness of nurses to follow innovations.

There was no statistically significant difference between the mean scores of the nurses on the overall BRPF scale and its subscales according to their status for patient rights education ($p > 0.05$, Table 7). The nurses who got education about patient rights, had lower scores on the subscales of 'human rights and values in health services', 'informing', 'consent', 'care and treatment' and 'application', the nurses who got education were generally more sensitive to patient rights. Teke et al., (2007) showed that there was no statistically significant correlation between the nurses' education status about patient rights and their mean knowledge and attitude scores related to patient rights ($p > 0.05$). It can be suggested that nurses who are educated about patient rights are more sensitive.

CONCLUSION

The sensitivity of the nurses in surgical services to patient rights was high; it was determined that the nurses who were at the ages of 29 or younger, undergraduates, worked 1-5 years and got educated about patient rights, had higher levels of patient rights sensitivity. According to these results, more time should be allocated for this subject in the curricula before the graduation and training programs should be planned for nurses after graduation according to their age groups, working years, their status for getting the education on patient rights, for raising the awareness of nurses about the sensitivity to patient rights, for knowing the problems related with patient rights, for providing solution. The effect of provided education on the knowledge, attitudes and behaviors of nurses should be monitored. It may also be beneficial to conduct further studies in larger groups, including other members of the healthcare team, for determining the different factors that can affect the sensitivities of surgical nurses to patient rights.

Chapter 281

CONTROL AND ERADICATION OF ANIMAL BRUCELLOSIS

Mustafa Sencer Karagul*

Kartepe Vocational School of Equine Science,
Kocaeli University, Kocaeli, Turkey

ABSTRACT

Brucella spp. causes brucellosis, which is one of the most common zoonotic diseases and which brings about important problems related to health and economy. Direct or indirect contact with infected animals or their products is the main way of transmission of the infection. If brucellosis in animal reservoirs can be controlled, it will be easier to see a decline in the incidence of human brucellosis as well. The primary means of fight against animal brucellosis includes test-and-slaughter programs, routine screening, and control of animal movement, hygiene, herd management, and vaccination. In many countries, achieved success in control and eradication of brucellosis has a governmental regulation/legislation background. Control and eradication require effective collaboration between veterinarians and all the sectors of public health. The aim of this chapter is to reveal general aspects of control and eradication of this disease and it specifically gives information about the case in Turkey.

Keywords: brucellosis, control, eradication, vaccine, vaccination

INTRODUCTION

Almost 2/3 of human pathogens are zoonotic and more strikingly, ¾ of emerging and re-emerging diseases in humans are also zoonoses (Godfroid et al., 2013). Some precautions against specific zoonoses and zoonotic agents in animals and animal products used to prevent outbreaks of food-borne infections and intoxications have been revealed by the European

* Corresponding Author's Email: msencerk@hotmail.com.

Union (EU) through some specific regulations (Council Directive 92/117/EEC). Problems related to brucellosis clearly illustrate the need for a ‘One World, One Health’ strategy because if the public and animal health authorities work together, control and subsequent eradication of the disease could be achieved (Perez-Sancho et al., 2015). The term ‘eradication,’ in veterinary medicine, means eliminating an infectious agent and up to now very few diseases have been eradicated. On the other hand, ‘control of a zoonotic disease,’ refers to all the measures taken in order to decrease the incidence and prevalence of the disease in an animal population (Minas, 2006).

The control of animal brucellosis has been successfully implemented with the help of the combination of vaccination and test-and-slaughter programs in the developed countries. They also succeeded in controlling human brucellosis via milk pasteurization in combination with effective surveillance of the disease and the control of animal movement. (McDermott & Arimi, 2002; Pappas et al., 2006). For this reason, it has been recommended that communities’ needs and perceptions should be included in any disease control strategies (Marcotty et al., 2009). For any strategy used for controlling and eradicating brucellosis to be effective, it is necessary for farmers to support the process and collaborate with other stakeholders (Ragan, 2002). It is also necessary for the sectors of public health and veterinarians to collaborate (Yumuk & O’Callaghan 2012).

CONTROL AND ERADICATION

Decreasing the prevalence and incidence will lead to minimal effects on human health and regional economy. For brucellosis, the control measures taken should include monitoring brucellosis-free flocks and preventing the spread of the infection, reducing the rate of infection, and making animals more resistant (Minas, 2006). According to OIE, there are some specific requirements for a country/zone to be considered as free from brucellosis (Resmi Gazete, 2009; Perez-Sancho et al., 2015):

- Bovine brucellosis should be declared as notifiable
- An official veterinary control system including the whole bovine population should be established
- The flock prevalence of the disease should be lower than 0.2%
- There should not be any vaccination that has been conducted in the last three years
- All flocks should be subject to periodical serological testing
- All reactors should be culled
- New animals should be introduced to the regions which are parts of officially brucellosis-free herds

In order for an eradication program of brucellosis to be implemented, flocks should be under strict surveillance and movement control, individual identification of animals should be supplied and veterinary service, which is effective and well organized, should be adopted for surveillance and laboratory testing in place (Minas, 2006). When choosing the best approach to deal with the disease, the prevalence of animal brucellosis should not be considered as the only parameter by the decision makers because in order to use the most sufficient control

strategy in each region, other epidemiological and economic aspects should also be taken into consideration (Perez-Sancho et al., 2015).

Even if all the tools to be used to eradicate the disease are existent in eradication and control program, adequate surveillance is a critical first step (Ragan, 2002; Yumuk & O'Callaghan, 2012). Permanent identification of animals is a fundamental element in a successful surveillance program (Ragan, 2002). After the initial phase, where the infection is controlled through obligatory vaccination, vaccination is restrained step by step and it is eventually banned; however, in order to eradicate the infection, a 'test-and-slaughter' policy is carried out (Godfroid et al., 2013).

The most influential strategies used to control this pathology in livestock include strict biosafety, management precautions and test-and-slaughter strategy. There are 3 main strategies which are used in brucellosis control of domestic animals: hygienic measures, test-and-slaughter programs, immunization. As optimal results are gathered through using at least two of them together, the use of only one of these measures is not effective enough (Nicoletti, 2010). To be able to be successful in the program, which includes animal identification, animal movement control, economic compensations, and other complimentary tools should also be added to these already-known strategies (Crespo et al., 2012).

In terms of biosafety and management, what is necessary includes both finding the disease and eliminating it and also doing it before it reaches susceptible herds. If there is success in identification, control and eradication of the disease before it spreads, then it is possible for eradication to be achieved. Understanding of the epidemiology and pathogenesis of brucellosis in eradication is a very important step (Ragan, 2002). Precautions of hygiene and management against brucellosis must emphasize decreasing the possibility of contact with viable *brucella* which includes animals that are infected and contaminated environments. For this reason, in order to prevent the disease from entering in an epidemiological unit, suitable biosecurity precautions should be taken. Hygiene precautions are used to decrease the possibility of contact with viable bacteria and they are also used to control and constrain the bacterial load in the environment. (Perez-Sancho et al., 2015).

It is believed that the existence of the disease in wild animals depends on its existence in domestic animals. The point of connection is that fact that aborted foetuses and foetal membranes are carried by carnivores and it also causes the disease to spread to domestic herds and pastures which are free from brucellosis (Thimm, 1982). Only if infected animals' prevalence is 2% or less, the flocks are kept in a strictly controlled environment and they are protected from the re-entry of infection is it possible for an eradication program including a test-and-slaughter policy to be implemented on the related economic grounds (Minas 2006, Yumuk & O'Callaghan, 2012).

The main objective of the test-and-slaughter approach is detecting and removing possible sources of infection, which will automatically prevent the circulation of *brucella* strains. Because of the silent carriers that are keeping the pathogen in the flock, there might be abortion storms if the immunity of the herd decreases. This strategy seems most useful when there are necessary economic resources and veterinary expertise in places where the prevalence of the disease is low (Perez-Sancho et al., 2015).

Despite the fact that the counter actions against brucellosis in small ruminants have been characterized well, socio-economic factors affect the selection of the most appropriate control measures in most endemic areas. For instance, because pastoral ecosystems, which are traditional ways of management used in low-income areas in which *B. melitensis* is endemic,

have led to the continuation of the disease as it is difficult to detect the disease in the early stages and to take necessary control precautions (Perez-Sancho et al., 2015). It was stated that it is possible to implement eradication through a test-and-slaughter policy if sheep and goats are controlled strictly and the type of husbandry is not extensive and grazing of herds is not common (Minas, 2006).

It must also be taken into consideration that the tests used in diagnosis cannot detect all infected animals and they might give false negative results because of the period of incubation, latency or the criteria that are considered for the interpretation of the results (Minas, 2006). For this reason, for the success of the test-control strategies used in the eradication programs, the certainty of the approval of laboratories and diagnostic tests are mentioned as the important factors (Perez-Sancho et al., 2015; Ragan, 2002). For instance, it is stated that the silent carriers of the disease, which are the infants infected congenitally in utero or through the ingestion of contaminated milk or colostrum, may still be seronegative by the time a problem in their reproductivity appears (Perez-Sancho et al., 2015). Therefore, it is necessary to integrate laboratory testing with epidemiological investigation in order to overcome false-positive findings of laboratories as *Brucella* bacteria might be used as potential bioterror agents (Godfroid et al., 2005).

In the case of bioterrorism, it is very important to differentiate between true brucellosis and other diseases which appear in the differential diagnosis of brucellosis. Among these are infections which appear because of cross-reactive bacteria in the serology of brucellosis, such as YO9 (Gourdon et al., 1999). It was stated that there might be the possibility of having laboratory-acquired infections due to the inhalation of infective aerosols which are produced accidentally by microbiological techniques. Thus, it is necessary to utilize biosafety level 3 cabinets in the laboratories which include work related to *Brucella* spp. (Godfroid et al., 2005).

At present, trading takes place between countries which are 'officially free from brucellosis'. Alternatively, the herds/flocks, which are brucellosis-free, might also be preferred for trading. But, there are also some other possibilities; namely, traded animals might be recently infected but the infection might not have been detected yet, they might be infected during transportation or when they are together with other animals at market places. It shows that tests which are recommended for trading can detect acute infections in animals. It must also be taken into account that the only diagnosis of certainty is bacteriology (Godfroid et al., 2013).

Generally, endemic regions are defined as the ones that are structurally weak and the ones which might become worse as proficient veterinary service requires the use of current vaccines effectively. This requirement relates in part to some of the limitations of currently available brucellosis vaccines, and it seems likely that a perfect vaccine could greatly facilitate control and eradication (Godfroid et al., 2011). It was stated that if the population's resistance to disease could be increased with the help of vaccination, it could be possible to control brucellosis. For this reason, vaccination is regarded as more acceptable and efficient when compared to other methods used for this purpose. Moreover, depending upon the vaccines' practical use to eliminate the clinical signs of brucellosis, the environment would be less contaminated and the population's risk to the infection's agent would decrease (Minas, 2006).

TREATMENT

Winning the fight against human brucellosis depends upon the control and eradication of animal brucellosis (Boschioli et al., 2001; Corbel, 1997; Godfroid et al., 2005). Control and prevention are significant for animals; when it comes to humans, treatment gains more importance. Brucellosis is mentioned as ‘cattle brucellosis’ and ‘sheep-goat brucellosis’ in notifiable animal diseases list of ‘the Regulation of Reporting of Notifiable Animal Diseases’ (Resmi Gazete, 2011). As stated in the *Regulation of Fighting Brucellosis*, it is obligatory to notify the authorities in the case of the existence or the suspicion of brucellosis in cattle, sheep and goats. In the same regulation, it is also pointed out that it is prohibited to take action to treat brucellosis in cattle, sheep and goats (Resmi Gazete, 2009).

Antibiotics have been utilized with success in the treatment of some dogs affected by *B. canis*. Even though it is required to use two different antibiotics simultaneously, the use of only enrofloxacin seemed to be successful in one case. It has also been stated that no treatment has proved to be successful to eliminate *B. canis*. The organism of the disease might appear to have disappeared but it is possible for it to reappear in tissues such as lymph nodes, spleen, uterus and prostate (CFSPH, 2012). In a study by Wanke et al. (2006), enrofloxacin could not effectively treat canine brucellosis but it could help them remain fertile and it also prevented them from aborting and infecting the puppies and spreading the microorganisms during parturition.

When it comes to humans, as *Brucella* bacteria can adapt to the environmental conditions that are met during their replicative niche (Seleem et al., 2008) and their intracellular localization, the rates of treatment failure and relapse are high and they are changeable depending on the combination of drugs and the compliance of patients (Seleem et al., 2010). Because it is highly probable for monotherapies with single antibiotics to relapse, the best treatment for brucellosis is using a combination of two antibiotics. The best option, especially for the acute brucellosis cases, seems to be utilizing doxycycline in combination with streptomycin (DS) as it leads to fewer side effects and relapses (Matthew & Leland, 2004; Seleem et al., 2010). World Health Organization (WHO) has regarded DS combination as the standard treatment against brucellosis for years. In 1986, joint FAO/WHO committee suggested using doxycycline and rifampin (DR) together for 6 weeks for the treatment of adult acute brucellosis (WHO, 1986). However, the studies comparing and contrasting the effects of DR with traditional DS found out that DR, particularly in patients suffering from acute brucellosis, is not as effective as DS (Solera et al., 1997).

If the treatment is inadequate, severe and debilitating chronic courses and long-term sequelae may appear. For this reason, the most important aim is two-folded: controlling acute illness and preventing some possible complications and relapses. In the treatment, utilizing at least two synergistic antibiotics, including doxycycline, rifampin, streptomycin (or other aminoglycosides) or trimethoprim-sulfamethoxazol is a necessity for prolonged chemotherapeutic regimens (Godfroid et al., 2011). After the treatment is over, titers will decrease step by step but IgG antibodies decrease faster than IgM antibodies. Even though there is no active infection, in some cases, low tiers of IgM antibodies might persist for months or years (Doganay & Aygen, 2003; Matthew & Leland, 2004). For this reason, measuring IgG is traditionally used to see whether the therapy is effective or not (Matthew & Leland, 2004).

VACCINATION

Immunization against agents of infection has become a key element in the process of controlling the most significant infectious diseases since Eduard Jenner's description of first vaccine against smallpox in 1796 (Perez-Sancho et al., 2015). The only way to control and eradicate brucellosis is believed to be vaccinating all the hosts which are susceptible and eliminating all of the infected animals in the regions in which the prevalence of the disease is high (Briones et al., 2001).

The most common vaccines which are used against bovine brucellosis are *B. abortus* strain 19 and RB51, which were recently approved by USDA and which do not interfere with serological diagnoses (Moriyon et al., 2004). As can be seen in all highly contagious diseases, the effect of vaccination augments as the coverage of vaccination increases. Only if the vaccine is a high quality one and if it can be administered to at least 80% of the risk-group animals, sufficient protection can be possible (Minas, 2006).

B. abortus S19 and *B. melitensis* Rev1, which are considered to be the best two attenuated vaccines developed in the past century, have both a good degree of residual virulence. Rev1 vaccine is not only used against *B. melitensis* in sheep and goats but also against *B. ovis*. S19 strain has appeared as a result of accidental attenuation, which was due to the long laboratory storage under insufficient conditions and Rev1 strain is a revertant of a streptomycin-dependent mutant with a known ribosomal mutation and possibly other genetic defects (Godfroid et al., 2011). The first step for the eradication of *B. melitensis* infection in the areas, where it is endemic or where the prevalence of the disease is high, is controlling the disease through the vaccination of animals. For small ruminants, the vaccine used is Rev-1 vaccine. An alternative method for brucellosis control, particularly in the endemic areas where the prevalence of the disease is more than 5%, is vaccination of all animals in the flock/herd regardless of their age. There are good results in different areas with sufficient financial resources (Minas, 2006).

There is evidence that Rev1 vaccine is resistant to streptomycin, which is used in the treatment of human brucellosis and S19 vaccine is resistant to penicillin G. In addition, it is stated that RB-51, which was prepared for cattle, has resistance to rifampicin, which is again used against human brucellosis (Grillo et al., 2000). S19 and Rev1 vaccines carry a smooth (S) lipopolysaccharide (S-LPS) and an O-polysaccharide (PS), which is similar to brucellae that are of wild type. In the controlled experiments, only one dose of Rev1 provides 80-100% protection against challenge strains (Barrio et al., 2009).

Rev1 strain is regarded as the reference vaccine to immunize the sheep and goats which are at risk for infection and it needs to be compared and contrasted with other vaccines (OIE, 2009a). The disadvantages of this vaccine include its causing abortion during pregnancy, its interference in serological diagnosis, its virulence for human beings, its resistance to streptomycin and its tendency to dissociate into rough mutants which are ineffective (Godfroid et al., 2011; Seleem et al., 2010). Moreover, because it might be difficult to discriminate the antibody response to vaccination from the ones seen after field infection, they might interfere with control programs. There are still attempts to develop new live attenuated rough vaccines for *B. melitensis*, which are deprived of O-side chain. These vaccines need further evaluation in field experiments (Adone et al., 2008; Blasco, 1997; Garin-Bastuji et al., 1998).

It is possible to partially go beyond these limitations through vaccinating animals conjunctivally when they are younger than 4 months old. It will decrease the amount of interference in serological diagnosis and abortions caused by vaccines. Thanks to a minimal amount of personal protection, Rev1 vaccine becomes safe and there are well-established protocols of quality control (Godfroid et al., 2011). Despite the insufficiency of related studies, it is pointed out that *B. melitensis* in cattle might be controlled with the help of S19 vaccine. All the successful programs in cattle have utilized S19 except for a number of countries with good conditions of geography and management (Godfroid et al., 2011). Thanks to adult vaccination with S19, it is possible to increase herd resistance and to decrease shedding of *B. abortus* at calving or abortion (Ragan, 2002). When animals are younger than 4 months old, conjunctival vaccination including smaller doses will reduce serological interference and udder infections. S19 vaccine used in cattle is both economical and it is not resistant to antibiotics. Even though it is not as virulent as Rev1 for humans, it needs minimum level of individual protection (Godfroid et al., 2011).

Vaccination of both rams and ewes is the most feasible way of providing the control of *B. ovis* in places having a high prevalence of infection because both of them play an important role in the transmission of infection. There is not a certain vaccine against *B. ovis* but live *B. melitensis* strain Rev1 vaccine is appropriate for stimulating immunity against *B. ovis*. It is also possible to use a single dose of Rev1 (10^9 cfu) given subcutaneously or conjunctivally to overcome *B. melitensis* infection (OIE 2015). There is not an existing vaccine for pigs (Godfroid et al., 2011). In China, *B. suis* biovar-2 vaccine is used to immunize pigs but in order to recommend strain 2 vaccine for general use, the results obtained in China should be confirmed (OIE, 2009b).

It is stated that RB51 vaccine might lead to abortions and shedding. Its use should be limited with animals which are not pregnant. RB51 can induce abortions and can be excreted (Moriyon et al., 2004). It is also claimed that RB51 vaccine is more attenuated and as a result, it is considered to be less dangerous than S19 and there are only a few human cases mentioned (Ashford et al., 2004; Godfroid et al., 2011). But for human brucellosis, the number of unreported human cases might be more as the lack of anti-O-PS antibodies makes RB51 difficult to detect in standard laboratory tests. For this reason, it is necessary to keep biosafety practices while utilizing RB51. A further disadvantage of RB51 is the resistance to rifampin since this antibiotic is more preferable than streptomycin or gentamicin for treatment (Godfroid et al., 2011).

There have been several attempts to develop a killed *Brucella* vaccine for human use but so far, they have not been utilized extensively because there is no long-lasting immunity (Matthew & Leland, 2004). There is not an existing vaccine for human brucellosis (Godfroid et al., 2005; Godfroid et al., 2011; Yumuk & O'Callaghan, 2012). Under the WHO global program on vaccination and immunization, priority should be given to the development of such a vaccine (Godfroid et al., 2005).

THE FIGHT AGAINST BRUCELLOSIS IN TURKEY

In Turkey, the first brucellosis case was identified by Husamettin Kural and Mahmut Sabit Akalin in 1915 in a soldier, who was being treated in Istanbul Kuleli Military Hospital

(Celebi, 2003; Cevik, 2001; Golem, 1949; Iyisan et al., 2000). In the Turkish context, the first documented case of brucellosis, which was confirmed by a laboratory was in 1915 despite the fact that it is believed that Florence Nightingale got this disease during the Crimean War in Turkey (Young, 1995; Yumuk & O'Callaghan, 2012). In many regions, pasteurizing fresh milk protects the city population from this disease; however, there is still some risk for people who are in direct contact with infected animals and who consume fresh milk (Kuplulu & Sarimehmetoglu, 2004; Yumuk & O'Callaghan, 2012).

It is stated that the control of the disease is the responsibility of veterinarians as almost all cases of human brucellosis are originated from animals (Nicoletti, 2002; Yumuk & O'Callaghan, 2012). In this context, the precautions against this anthroponozoonosis should include the control and eradication of the disease in the animal reservoir (Thimm, 1982). The initial work on the control and eradication of brucellosis started in 1930 for *Brucella abortus* in cattle. In this sense, the Brucella Laboratory established within Ankara Etlik Institute of Veterinary Bacteriology and Serology moved to the Institute of İstanbul Pendik Veterinary Bacteriology and Serology in 1951. *Brucella melitensis* laboratory was founded in 1965 and later on, the production of *B. melitensis* Rev-1 started in 1969 (GTHB, 2012).

In Turkey, 'National Brucella Control and Eradication Project' was implemented in 1984 by the Ministry of Agriculture and Forestry. For this project, a 26-year-period (1984-2010) was determined and vaccination of calves, labs and ewes was the main aim. (GTHB, 2012; Iyisan 2006). After this project, the authorities tried to find out about the prevalence of the disease in cattle and sheep in 2011 and it was revealed that herd prevalence of brucella in cattle is 7.8% and in sheep it is 22.5% (GTHB, 2012).

Experts in the Ministry evaluated the results of the work carried out in 2011 on the prevalence of Brucellosis and focused on the strategies adopted by the countries to eradicate this disease. They decided that mass vaccination is the most feasible method and they also decided that mass vaccination should be through conjunctival vaccination of animals of all ages. In this context, 'The Project of the Control and Eradication of Brucella through Conjunctival Vaccines' started in 2012 and it is planned to continue for 10 years in cattle, for 6 years in sheep and goats (GTHB, 2012). After this mass vaccination which started in 2012, Brucellosis outbreaks and human cases were evaluated. Except for the vaccine-related abort cases in 2013, there are dramatic decreases in outbreaks and very significant declines in human cases. It is possible to state that the continuation of mass vaccination as well as other control and sanitary measures should be the main approach (Saytekin et al., 2015).

If brucellosis incidence in animal reservoirs is controlled, there can be a related decrease in the incidence of human brucellosis as well. After the long and successful efforts of developed countries which were able to control bovine brucellosis, there was also a visible decrease in the incidence of human infection. Therefore, the eradication of brucellosis can be achieved only if all the parties are involved in the process of finding a solution (Seleem et al., 2010).

Chapter 282

SMALL RUMINANT MORBILLIVIRUS

Ahmet Sait*

Pendik Veterinary Control Institute, Viral Diagnosis Laboratory, Istanbul, Turkey

ABSTRACT

Small ruminant morbillivirus (SRM), also known as ‘goat plague’, ‘Kata’, ‘syndrome of stomatitis-pneumoenteritis’ or ‘ovine rinderpest’, is a viral disease of sheep, goats and small wildlife ruminants characterized by fever, sores in the mouth, diarrhea, pneumonia, and sometimes death. The disease is considered to be a major barrier to the development of sustainable agriculture across the developing countries in the world. The global eradication of the disease has been targeted by the World Organisation for Animal Health (OIE) and the Food and Agriculture Organisation (FAO) by 2030. This chapter aims to share current information about the disease.

Keywords: goat, Kata, morbillivirus, peste des petits ruminants virus, sheep

INTRODUCTION

The genus *Morbillivirus* belongs to the virus family *Paramyxoviridae*, contains highly infectious viruses that spread via the respiratory route and causes immune suppression. Because of these features, they have a potential causing large outbreaks associated with high morbidity and mortality in previously unexposed humans and animals. *Small ruminant morbillivirus*, *Rinderpest morbillivirus*, *Canine morbillivirus*, *Newcastle Disease Virus* and *Measles morbillivirus* are some of these viruses. Recently, new morbilliviruses, *Phocine morbillivirus* and *Cetacean morbillivirus*, have been detected in marine mammals (Chauhan et al., 2009).

* Corresponding Author's Email: saitvet@gmail.com.

Small ruminant morbillivirus (SRM), also named as Peste des Petits Ruminants Virus (PPRV), causes a severe disease, Peste des petits ruminants (PPR), in sheep, goats and small wildlife ruminants. PPR was first described in the Ivory Coast in West Africa (Gargadennec & Lalanne, 1942). The disease has since been recognized as endemic in West and Central Africa (Scott, 1981) and in the north-east of the continent, Kenya and Uganda (Wamwayi et al., 1995), Sudan (Haroun et al., 2002) and Ethiopia (Reoder et al., 1994; Abraham et al., 2005). In 1987, it appeared in the Middle East and has since then been confirmed in Jordan (Lefevre et al., 1991), Pakistan (Amjad et al., 1996), southern India (Nanda et al., 1996), Turkey (Ozkul et al., 2002; Dagalp et al., 2015; Sevik & Sait, 2015). The detection of the disease in Tunisia (Ayari-Fakhfakh et al., 2010), Morocco (FAO, 2009) and Algeria indicates that the infection has reached the border of the European Union (Banyard et al., 2010). Moreover, the detection of the disease in the Thrace region of Turkey in 1996 has led to questioning the potential spread of the disease to other parts of Europe (Ozkul et al., 2002; Banyard et al., 2010). While this article was being prepared, the *World Organisation for Animal Health* (OIE) informed that the disease was detected in Bulgaria for the first time (OIE, 2018).

Etiology

The causal agent, *Small ruminant morbillivirus* (SRM), belongs to the genus *Morbillivirus* in the family *Paramyxoviridae* (Gibbs et al., 1979; Bailey et al., 2005). SRM has single stranded nonsegmented negative sense RNA genome, which encodes six structural proteins: nucleocapsid protein (N), phosphoprotein (P), matrix protein (M), fusion (F) protein, hemagglutinin (H), and polymerase (L) protein. The P gene also encodes two non-structural proteins, C and V, which are thought to function in viral evasion of the host immune responses (Nanda & Baron, 2006). Due to its biological and antigenic properties, it has been closely related to *Rinderpest morbillivirus* and other morbilliviruses (*Canine morbillivirus*, *Measles morbillivirus*, *Phocine morbillivirus* and *Cetacean morbillivirus*) (Gibbs et al., 1979; Baron et al., 2011). Molecular techniques and nucleic acid sequence analysis studies have proven that the SRM is completely separate from the *Rinderpest morbillivirus* (Gopilo, 2005). As a result of molecular epidemiological studies, the SRM has been divided into 4 different genetic lineages according to the F and N gene partial sequence analysis. It has been observed that there are nucleotide changes between SRM isolates in these 4 different genetic lineages that are compatible with the geographical distribution but do not express a separate serotype or strain (Chard, 2008). According to geographical distribution, lineages I and II have been found in West Africa, whereas lineage III has been found in eastern Africa, Arabian Peninsula and southern India. Lineage IV is found in the Middle East, south Asia and China (Dhar et al., 2002; Banyard et al., 2010; Kwiatek et al., 2011). Used as vaccine strains, Nigeria75/1 strain was located in lineage I, and Sungri96 strain was located in lineage IV (Shaila ve ark., 1996; Dhar ve ark., 2002; Muthuchelvan, 2006).

Hosts

SRM is an important pathogen of small ruminants and clinical disease is seen in sheep and goats and has been described in wild small ruminants (Hamdy et al. 1976; Reoder and Obi 1999). However, subclinical infections have been reported in cattle, which formed cross protection against virus (Diop et al. 2005). Buffaloes, camels and pigs may be infected with the virus, but show little or no clinical symptoms (Chauhan et al., 2009). Antibody production against virus was also detected in camels (Roger et al., 2001). SRM could infect wild animals both naturally and experimentally. Antelope and other small wild ruminants including Laristan sheep (*Ovis gmelini laristanica*), Dorcas-type gazelles (*Gazella granti*), gemsbok (*Oryx gazelle*), and the Nubian ibex (*Capra ibex nubiana*) are severely affected by the disease (Hamdy & Dardiri, 1976; Abu Elzein et. al. 2004; Gur & Albayrak, 2010). Balamurugan et al. (2012) reported that the virus obtained from frozen tissue taken from Asian lion (*Panthera leo persica*) belongs to lineage IV according to the partial sequence of N, F and M genes. At the same time, this report was the first report on SRM isolation in Asian lions. The disease does not pose any risk to humans (OIE, 2013).

Transmission

Contagion of SRM from infected to susceptible animals is via by direct contact, close contact and oral routes (Chauhan et al. 2009). Since the virus has lost its viability in the outdoors in a short time, the most important way of transmission is the close contact of the patients in the acute febrile period with the susceptible animals. The aerosol droplets and stools of the infected animals contain high amounts of virus. Small infective droplets spreading to the area, especially by sneezing and coughing, transmit the disease to the susceptible animals through respiration. Besides the close contact, the contaminated bed, feed and water also form an additional source of contamination (Gopilo, 2005). It has been found that viral antigens are scattered in stools until the 11th week after SRM infection (Ezeibe et al., 2008). This suggests that naturally infected animals may pose a significant risk for susceptible populations.

As a current issue, the role of wildlife in the transmission of SRM attracts attention. However, since there is not enough epidemiological data yet, more detailed investigations are needed (Baron et al., 2011).

Clinical Signs

SRM infection is characterized by different clinical patterns ranging from perakut, acute and subacute depending on the various factors such as species and age of the animal, virulence and amount of the virus, secondary infections, etc. (Diallo, 1988; Lefevre ve Diallo, 1990). The mortality rate in the infected herd may vary between 10-90%, and especially in naive population it can be up to 90%. These rates are usually lower in endemic areas, where mortality may be 20% or less, and serosurveillance is sometimes the only indicator of infection. The incubation period varies between 3-9 days depending on the amount of

virus and the route of infection (Baron et al., 2011). During the incubation period, the virus replicates in oropharyngeal lymph nodes and then spreads to other tissues and organs. After the incubation period, body temperature increases by 40-41,5°C. A peracute form that results in death a few days after the onset of fever is rare (Gibbs et al., 1979).

In acute form, which is common, the fever lasts for up to a week and the symptoms of the disease are seen in this form. In this period, leucopenia, hyperemia in the mouth mucosa, congestion in the nose and eye mucosa and oculonasal discharge are remarkable. After the fever begins to rise, scales (accumulations of surface skin cells, such as seen in *dandruff*) and erosive lesions begin to appear in the mouth and vulva. Initially, the foci of necrosis in small gray-white color and dot shape grow and spread over time. Then, necrotic areas start to appear on the gums, dental pad, palate, lips, inner aspects of the cheeks and upper surface of the tongue. These areas increase in number and size and join together. The necrotic foci in the mouth and on the cheek rapidly become eroded and covered with yellow-matte white cell destruction. The erosions can spread to the lower face of the tongue and the pharynx. Then, the necrotic areas are covered with exudate released from the inflamed tissue. Excessive salivation and water consumption are seen in sick animals; moreover, these are restless, depressive and anorexic. They have superficial respiration and their breath has a bad smell (Baron et al., 2011). The serous nature of the mouth, nose and eye fluids at the beginning is intense and yellow due to secondary bacterial infections. Diarrhea occurs 1-3 days after the onset of the infection and death generally occurs 5-12 days later. Abortions may occur during infection (FAO, 1999).

The subacute form of the disease is characterized by mucosal discharge that lasts for 2-3 days and does not attract much attention, with a moderate increase in body temperature for 1-2 days. There is no death in this form of the disease (Diallo, 2006).

Diagnosis

The use of rapid, specific, sensitive laboratory methods in the diagnosis of SRM is crucial for the effective implementation of control programs (Diallo et al., 1995). The disease can be confused with cattle plague, foot and mouth disease, pasteurellosis, ectima, sheep and goat pox, pneumoniae, bluetongue, coccidiosis, colibacillosis, poisoning, cryptosporidiosis and pestivirus infections. Although infection is suspected in the light of clinical findings, laboratory tests are essential for differential diagnosis (Diallo, 1988; Scott, 1990). Laboratory tests include viral antigen detection, virus isolation, nucleic acid detection and detection of specific antibodies in serum samples taken at 14 days intervals (Gopilo, 2005). The collection of samples at the correct time is important to achieve diagnosis by virus isolation. Anticoagulant-treated blood and swab samples (conjunctival discharges, nasal secretions, buccal and rectal mucosae) should be taken from live animals in the acute phase of the disease when clinical signs are apparent (OIE, 2013). Tissue samples (pulmonary, spleen, lymph nodes) should be obtained from dead animals for virological diagnosis within the 2 hours after the death. The samples should be delivered to the laboratory in the cold chain as soon as possible.

There are several methods available for the diagnosis of SRM. Some of them are virus isolation, reverse transcription polymerase chain reaction (RT-PCR) and enzyme-

linked immunosorbent assay (ELISA). Because it's a cheap method that allows to work with many samples, ELISA is now widely used in the labs (Libeau et al., 1995). Virus isolation in cell culture is a specific technique that needs experience and time, but it has low efficiency. For this reason, it is not widely used in routine diagnosis. RT-PCR allowing to nucleotide sequencing and subsequent phylogenetic analysis and the real time RT-PCR (rRT-PCR) performing quantification of viral loads are the current diagnostic methods for all morbillivirus infections (Forsyth & Barrett, 1995; Shaila *et al.*, 1996; Couacy-Hymann *et al.*, 2002).

Protection and Control

SRM control measures mainly involve disease surveillance, vaccination, stamping out and to strict control of illegal or uncontrolled animal movements (Abubakar et al., 2011).

Surveillance should aim identification of the prevalence of the disease, new outbreaks and disease free areas, monitoring of the disease trends, and informing what should be made at critical control points. Risk-based surveillance is the most cost-effective way to identify and monitor the disease. While high-risk based surveillance focuses on the detection of incursions at critical points, low risk based surveillance focuses on early detection and the response of disease in areas free from disease (SADC 2012).

Since the prevention of illegal animal movements is difficult to implement successfully in the Middle East, Africa and Asia, where the disease is endemic, vaccination is regarded as the most basic way of controlling PPR (Diallo, 2003). Sheep and goats probably do not have multiple infections with SRM throughout their economic lives. Those animals vaccinated with Nigeria75/1 vaccine strain have up to 100% immunity and 12 months of protection against the disease (Awa et al., 2002). Neutralizing antibodies are responsible for immunity. SRM specific neutralizing antibodies were detected on the 16th day of vaccination (Gulyaz et al., 2005). It has been reported that vaccination is safe in field trials and can be used easily even in pregnant animals (Diallo et al., 1995). Maternal antibodies can be detected up to 6 months in lambs and kids born from vaccinated mothers; but it can provide protection for 3.5 months in the lambs and 4.5 months in the kids. For this reason, lambs should be immunized in the 4th month and the kids in the 5th month (Awa et al., 2002). It is considered that the immunity is lifelong in animals recovering from the disease (OIE, 2013).

Treatment

There is no specific treatment for PPR but antibiotics and other supportive treatment may prevent secondary infections and decrease mortality (OIE 2013).

Chapter 283

ULTRA-HIGH MOLECULAR WEIGHT POLYETHYLENE FOR MEDICAL APPLICATIONS

Merve Dandan Doganci* and Erdinc Doganci

Department of Chemistry, Kocaeli Vocational School,
Kocaeli University, Kocaeli, Turkey

ABSTRACT

Ultra-high molecular weight polyethylene (UHMWPE) is a subset of the engineering thermoplastic polymers with extraordinary mechanical and physical properties with a molecular weight of $2\text{--}6 \times 10^6 \text{ g mol}^{-1}$. It is well known that UHMWPE has a great complex of convenient properties including thermal stability, wear resistance, and high impact strength, compared to customary polyethylene attained at low pressure. Additionally, UHMWPE has exceptional sound dampening characteristics, excellent electrical insulating properties, superior dielectric, chemical resistance, and low moisture permeability. All these inherent properties have enabled it to find widespread usage in various applications. This polymer has been extensively utilized in implants and orthopaedics as a biomaterial for total joint replacement applications since the 1960s. It enables effective transfer load due to having extremely long chains. It is so flexible and light, has less weight, good impact strength when compared to metals. Recently, all these outstanding properties have enhanced the demand for this polymer for biomedical applications, including artificial hips, knees, elbows, as well as in shoulders, spinal disks, and wrists. The morphological structure and properties of UHMWPE and its applications for the manufacturing of medical devices were discussed in this chapter.

Keywords: implants, medical applications, total joint replacements, UHMWPE

INTRODUCTION

UHMWPE is a linear, low-pressure polyethylene homopolymer with a very long chain. It is one of the most important high performance polymers owing to extraordinary physical and mechanical properties: excellent impact and wear resistance, very low coefficient of friction, ease of manufacture, high impact toughness, outstanding dielectric properties, excellent aesthetics, noise and energy attenuation, good abrasion resistance, high resistance to cyclic fatigue, high fiber modulus and toughness, very low service temperature, resistance to radiation, and more (Hambir, 2000; Keller et al., 1994; Rein et al., 2007; Yilmaz et al., 2017; Živić et al., 2014).

Due to high impact strength and abrasion resistance properties of UHMWPE, it has the low friction coefficient which yields a self-lubricating nonstick surface. Besides, UHMWPE has a very low water absorption, high chemical and corrosion resistance, stability and biocompatibility in the body and it is one of the most available and cheap polymeric materials (Gabriel et al., 2010; Selyutin et al., 2010).

As the chemical structure and molecular architecture, UHMWPE is rather similar to high-density polyethylene (HDPE) differing in the average molecular chains lengths and molecular weights. Because it is produced by a process in suspension with Ziegler-Natta catalysts, which assigns the getting of plastics with molecular weight in the range of two and six million g/mol is 10–100 times higher than that of HDPE, it's called as "ultra-high" in linear polyethylene class (Haas et al., 2013; Kelly, 2002; Morais et al., 2017; Rein et al., 2007; Salles & Goncalves, 2003). The physical properties of UHMWPE in comparison to HDPE were summarized in Table 1.

Table 1. Typical physical properties of UHMWPE and HDPE
(Fang et al., 2003; Kurtz, 2004)

Property	HDPE	UHMWPE
Molecular Weight (10^4 g/mol)	0.05-0.25	2-6
Melting Temperature (°C)	130-137	125-138
Poisson's Ratio	0.40	0.46
Specific Gravity	0.952-0.965	0.932-0.945
Tensile Modulus of Elasticity (GPa)	0.4-4.0	0.8-1.6
Tensile Yield Strength (MPa)	26-33	21-28
Tensile Ultimate Strength (MPa)	22-31	39-48
Tensile Ultimate Elongation (%)	10-1200	350-525
Degree of Crystallinity (%)	60-80	39-75

Owing to outstanding physical, chemical, and mechanical properties, it has been employed in many successful applications in different areas such as pulleys, textile, paper, the sliding parts of production lines, machinery, bumpers, mining, naval ropes, bearings, high-performance fiber products, artificial joints replacement in the human body (Forte & Ronca, 2017; Shafiee et al., 2014; Yilmaz et al., 2017).

UHMWPE FOR MEDICAL APPLICATIONS

UHMWPE is an ideal material for total joints with extremely large molecular chains which allow it to be used as a bearing surface and highly entangled chains make it resistant to wear. In 1962, Sir John Charnley used UHMWPE for joint articulation for the first time instead of polytetrafluoroethylene (PTFE) component because of its extensive wear resistance, lower friction and biocompatibility and it has been the crucial standard to produce one of the articulating surfaces of total knee, shoulder, and hip prostheses as well as elbow, ankle, total disc replacements (Musib, 2011). The main demands for a medical implant device in total joint replacements are low wear and friction, biological stability, biocompatibility, high toughness and creep resistance (Barbour et al., 1999).

To be used for biomedical applications, the resin powder must meet the essential properties as given in ISO 5834-1 and ASTM F648 standards (Kurtz, 2004). UHMWPE is initially fabricated as a micron sized resin powder (Fang et al., 2003; Musib, 2011). Later it is converted into consolidated form as a sheet, rod, or near shaped implant under high pressure and temperature by different thermoplastic-processing methods, including hot pressing, ram extrusion, sintering, compression moulding, spraying (hot flame, electrostatic) and gel formation for getting fibre (Figure 1). Because of the long polymer chain lengths, it has an enormously low melt flow index (MFI) or high melt viscosity of flow, 0.06 g/10 min, which restricts the processing of UHMWPE powder by conventional processing techniques, including screw extrusion, injection moulding, etc. (Gabriel et al., 2010). In the last step, it is machined from consolidated form into its final shape (Chilukoti & Periyasam, 2012; Kurtz, 2009).

The material must be sterilized before it's implanted into the human body. UHMWPE is generally sterilized with gamma irradiation in air or in a controlled environment with a sterilization dose of 25 and 40 kGy. The conventional sterilization techniques like autoclaving by steam cannot be used because the polymer begins to deform under high temperature conditions (Fang et al., 2003; Jones & Lauer, 1979). However, gamma sterilization can cause crosslinking, chain scission, and oxidation (Kurtz, 2004). The other methods for sterilization are ethylene oxide gas sterilization, low-temperature gas plasma sterilization, etc.

Figure 1. UHMWPE as a) resin powder form, b) sheet form, c) shaped form as a tablet.

The mechanical properties, oxidative degradation, and especially wear of UHMWPE are major problems for the longevity and performance of implants utilized in total joint replacements (Bracco et al., 2017; Fu et al., 2013; Fung et al., 2018; Jones & Lauer, 1979; Kurtz, 2004; Suñer et al., 2014; Wang et al., 1995; Wang et al., 1998). The bulk of the material is biocompatible, but particle debris due to wear are not biocompatible with the human body. It has been determined that millions of particles are taken apart from the surface of a total hip replacement (Kurtz et al., 1999). These wear debris can react with the tissue surrounding the bone, results in many problems for the patient such as cytotoxic reactions, inflammatory, and osteolysis (bone resorption). These reactions can cause loosening of the prosthesis. The improvement of the wear resistance could extend the clinical life span of total joint replacement and there has been ongoing research to solve the wear problem of UHMWPE (Affatoto et al., 2018; Baena et al., 2015; Holland et al., 2018). Oxidation is straightly correlated with the sterilization process of UHMWPE components. Sterilization with high-energy radiation causes high levels of oxidizing. Basically, high energy radiation creates free radicals which are highly reactive, and they easily react with oxygen causing oxidation on the backbone of the UHMWPE (Berry et al., 2012; Bracco et al., 2017). Besides, sterilization with gas or ethylene oxide (EtO) is the only method that effectively removes the oxidation (Affatoto et al., 2018; Del Prever et al., 2009; Mckellop et al., 2000). Oxidation causes to the formation of wear debris and makes changes in the mechanical properties of UHMWPE. Toughness of the UHMWPE composites is another important property for successful implementation of total joint replacements (Macuvele et al., 2017). High toughness restrains fracture and the creep resistance decreases the cold flow of the acetabular cup around the femoral head or into metal backings (Barbour et al., 1999).

CROSSLINKING OF UHMWPE

For nearly sixty years, UHMWPE has been commonly utilized as a bearing surface material in artificial bones and total joint replacements (Kurtz, 2009; Xiong et al., 2009). This semicrystalline polymer was selected for medical applications since it offers exclusive comprehensive properties like dynamic toughness, biocompatibility, high melt viscosity, high levels of strength, a low friction coefficient, creep resistance, and good wear resistance (Ansari et al., 2016; Macuvele et al., 2017; Pruitt, 2005). Owing to excessive adhesive/abrasive wear and resulted clinical complications like peri-prosthetic osteolysis are a major problem limiting the life span of implanted UHMWPE parts (Macuvele et al., 2017; Oral et al., 2009). Filling modifications for UHMWPE, like whisker, fiber, and particle reinforced UHMWPE composites have been researched to enhance its wear resistance rate (Xiong et al., 2009). Crosslinking of UHMWPE is an effective method to improve the wear resistance of polymer, to make it more durable and stable both in vitro and in vivo. First clinical research for crosslinked UHMWPEs demonstrated importantly a decrease in osteolysis and the wear rates, compared to original UHMWPE (Oral et al., 2008; Oral & Muratoglu, 2011). There are three classes of sterilization processes that have been utilized in crosslinking polymers such as chemical crosslinking using organic peroxides (chemical-induced crosslinking), ionizing radiation (radiation-induced crosslinking e.g., electron beam or γ -rays), and using silanes (silane compound-induced crosslinking) (Lewis, 2001;

Muratoglu et al., 2001). Crosslinking is generated interchain covalent bonding of the long chains of the polymer by the reaction of the free radicals by these ways (Ansari et al., 2016). Despite crosslinking enhances the wear resistance, it can also lead to a decrease in the hardness, toughness, elongation at break, ultimate tensile strength, resistance to fatigue crack propagation, elastic modulus, and yield strength of the UHMWPE (Muratoglu et al., 2001). In 2000s, ionizing radiation crosslinked UHMWPE materials were introduced to clinical practice. This method forms free radicals and generates crosslinking mostly in the amorphous phase of the polyethylene while these free radicals formed throughout ionizing irradiation in the crystalline phase remained active for a long time (Oral et al., 2010). Residual free radicals are trapped into the amorphous phase which caused decomposition of mechanical properties and reduced the molecular weight of the UHMWPE in the long-term oxidative degradation with diffused oxygen (Fu et al., 2013; Oral et al., 2008; Oral et al., 2009).

Therefore, to mitigate the crucial problem, the crosslinked UHMWPE polymers were thermally treated (melted or annealed) after irradiation. Post-irradiation re-melting or annealing is used to enhance oxidation resistance in the first generation crosslinked UHMWPEs (Figure 2). Annealing method does not eliminate free radicals in long-term oxidation, but it stabilizes the mechanical and crystallinity properties of crosslinked UHMWPE. Post-irradiation re-melting as another approach decreases the free radicals, it also reduces fatigue strength of the radiation crosslinked UHMWPE owing to crystallinity loss during melting. The first generation of crosslinked materials was utilized to quench the free radicals which resulted in successful reducing wear, but reduced the crystal size, crystallinity, and the mechanical properties of these polymers like ductility, strength, and fracture toughness (Fu et al., 2013; Sobieraj & Rimnac, 2009). Accordingly, a second generation of crosslinked UHMWPEs enhances mechanical properties and oxidative stability, besides preserving the wear resistance of the first generation. Recently, different processing approaches including mechanical deformation, high pressure crystallization after melting highly crosslinked UHMWPE, solid-state deformation, 3-step annealing post-irradiation, and incorporation of vitamin-E have been proposed for the second generation (Puppulin et al., 2016; Sobieraj & Rimnac, 2009).

Figure 2. Schematic representation of processing of crosslinked UHMWPE (Oral & Muratoglu, 2011).

As an important alternative approach, free radical scavengers and/or antioxidants have been successfully utilized to promote the radiation crosslinked UHMWPE instead of post-irradiation melting (Oral & Muratoglu, 2011). Vitamin E (α -tocopherol) is widely used as a

biocompatible, natural antioxidant agent in the medical fields and has been designed to enhance fatigue strength and mechanical properties of crosslinked UHMWPE compared to thermal treatments without sacrificing wear and oxidative stability (Oral et al., 2008). Because it can also act as an antioxidant during irradiation, it has successfully provided termination of free radicals to preserve long-term oxidative stability of UHMWPE. Conventional first and second generation crosslinking processes of UHMWPE are schematically depicted in Figure 2 (Oral & Muratoglu, 2011). Two methods of incorporate vitamin E in UHMWPE can be utilized to improve its wear resistance and mechanical properties; the first is to blend UHMWPE powders with vitamin E prior to irradiation and consolidation, and the second is to provide diffusion of vitamin E into molded and irradiated bulk UHMWPE blocks (Baena et al., 2015; Oral & Muratoglu, 2007; Oral & Muratoglu, 2011; Sobieraj & Rimnac, 2009).

TOTAL JOINT REPLACEMENTS

Joint replacement surgery takes out disturbed or diseased parts of a joint and repairs them partially or completely with new, synthetic parts called prosthesis. UHMWPE is the best material ever for most common artificial joints like hip and knee as well as shoulder, spinal, ankle or elbow prosthesis. UHMWPE parts of the joints are main load bearing surfaces that articulate against metal counterfaces like acetabular cup of the hip implants and tibial plateau of the knee implants. Each year, nearly 1.4 million or more joint replacement procedures are applied around the world. The hip and knee replacements are the most common joint replacements types.

Although ceramic-on-ceramic or metal-on-metal total joint replacements are experienced during the past decades, metal-on-UHMWPE is an international gold standard for damaged or diseased joints. UHMWPE coats the metallic surface of the joint to give a smooth surface and if the joints are not coated, friction can occur which is painful for the patients. Despite the enormous success and worldwide acceptance of this medical usage of UHMWPE, wear and resulting loosening problems limit the average life-span of the implants from 10-20 years as well as the specific conditions of each patient. There have been many efforts to solve this problem in UHMWPE at every stage of its productions from original to implanted forms (Baena et al., 2015; Kurtz et al., 1999; Li & Burstein, 1994). Especially, Kurtz and co-workers conducted numerous studies for the enhancement of UHMWPE and to improve its usage in total joint implants (Kurtz et al., 1999; Kurtz, 2004; Kurtz, 2009; MacDonald et al., 2018). Hydroxyapatite (HA), which is the major component of the mineral part of the human bone as reinforcement agent, was also used to improve the UHMWPE properties for biomedical applications (Macuvele et al., 2017).

Total Hip Replacements

The hip is the largest weight-bearing joint which consists of a ball and socket where thighbone joins with the pelvis and it is also enclosed by ligaments, muscles and cartilage inside the body. When some parts of the hip are destroyed, the joint movement becomes rigid

and here occur fractures in the cartilage. The cartilage cannot repair or replace itself like other tissues in the body. Therefore, once cartilage is damaged, it is gone forever, and replacement is needed. In total hip replacement, which is also called total hip arthroplasty, the disturbed cartilage and bone are removed and replaced with orthopedic implants. The general concept of an implant is a combined system consisting of an acetabular component, a femoral stem with a femoral head and a plastic liner which is made from UHMWPE fixed between the femoral stem and acetabular component (Burger et al., 2007).

Various materials are used in total hip replacement such as metals, ceramics and polymeric materials. As mentioned before, UHMWPE was first used in total hip replacements in 1962 as an alternative material to PTFE and later gamma irradiated UHMWPE was introduced in 1968 by Sir John Charnley. Initially, PTFE was used as an acetabular cup, but UHMWPE has been widely used for its low friction and high wear-resistance. At high temperatures or under high stress, UHMWPE is easily deformed, and the resulting wear problem limits the long-term performance of joint prosthesis. In late 1990s, highly crosslinked and thermally treated polyethylenes (HXLPEs) were clinically introduced for total hip replacements to enhance wear resistance of the UHMWPE liners (Kurtz et al., 2011; Kurtz et al., 2015; McKellop et al., 1999; Muratoglu et al., 1999). These UHMWPEs became the alternative bearing material and showed an extreme wear resistance on hip simulators compared with conventional UHMWPE. It offers design flexibility, including smaller sizes. However, its usage is new, its long-term performance is still being closely studied (Ghalme et al., 2016; Teeter et al., 2017; Yamamoto et al., 2017).

Knee Replacements

Total knee replacements (total knee arthroplasty) are the other most successful joint procedures. UHMWPE was first used in the 1960's in knee replacement surgery. It is reported by the Agency for Healthcare Research and Quality that 600,000 or more knee replacements are applied in the United States every year. UHMWPE is a crucial material for total knee replacements and there is no other bearing material instead of it in the knee (Kurtz, 2004).

Implant design and geometry also play significant role in preventing wear in knee arthroplasty. The design of knee implants is more complicated than hip implants. There are two basic total knee implants: The most common one is fixed-bearing knees where UHMWPE of the tibial component is fixed tightly to the metal component and the second one is mobile-bearing or rotating platform implants which UHMWPE insert can rotate short distance inside the metal tibial tray and facilitates movement of the insert relative to the tray. The mobile-bearing knee implant was designed to reduce contact stress on the bearing UHMWPE surface and resulting wear. Even though this design has advantages due to the potential for reduced polyethylene wear and component loosening compared to fixed-bearing knee, this has not been exactly proven by clinical studies yet (Aglietti et al., 2005; Bartel et al., 1986; Hernigou et al., 2018; Huang et al., 2007; Kim et al., 2018; McEwen et al., 2005; Utzschneider et al., 2009). In addition, the thickness of UHMWPE insert for tibial components is a major factor that effects the contact stress and it was reported that the thickness of UHMWPE layer in tibial components for knee replacement should be at least eight to ten millimeters (Bartel et al., 1986; Chakravarty et al., 2015).

Shoulder Replacement

Shoulder replacement (total shoulder arthroplasty) is less common than knee or hip replacements. The first shoulder replacement was performed in the 1950s to treat shoulder fractures and UHMWPE has been used in shoulder replacements since 1970s (Barret et al., 1987; Neer et al., 1982). Total shoulder arthroplasty consists of a humeral stem which is generally made of a metal and a glenoid component which is a concave shaped UHMWPE socket. UHMWPE is responsible for motion and load bearing. The glenoid part is generally fixed by bone cement (polymethyl methacrylate, PMMA) or uncemented press-fit fixation can be used, too (Van Vrekhem et al., 2018).

Several types of implant design and fixation of the glenoid component have been described. The round-backed, all UHMWPE components with peg fixation have been reported as clinically performing better than flat-backed, metal-backed, or keeled components (De Wilde et al., 2013). The thickness of UHMWPE of glenoid components varies from 3 to 15mm. It is reported that thicker components are subjected to reduce polyethylene wear and stress. The size of the glenoid part below 4mm is not suitable while the thickness of 6mm seems the optimal size for reducing wear whenever the soft tissue tension allows it (Harryman et al., 1995; Terrier et al., 2012).

Ankle Replacement

Total ankle replacement (total ankle arthroplasty) is a surgical procedure for the treatment of end-stage ankle osteoarthritis. Initial total ankle replacement with a ball and socket type implant on the basis of total hip replacement was designed by Lord and Marotte in 1970 (Kurtz, 2009; Jamal et al., 2014). The first generation of total ankle replacements consisted of two components, a concave UHMWPE articular surface on the tibia and a metal (usually cobalt-chrome alloy) convex surface on the taller component. In some of the designs, the tibial and taller components were reversed (Bonasia et al., 2010).

Second generation implants are consisting of a UHMWPE bearing surface combined with the talar component or tibial plate. In this type implants cement is not used. The third-generation implants composed of three parts with a third UHMWPE component as the mobile bearing meniscus which is constrained to a minimum (Kim et al., 2016). There have been many commercially available ankle implant types, such as cemented, uncemented types, and implant designs could be classified by implant properties and surgical technique (Jamal et al., 2014; Yu & Sheskier, 2014; Barg et al., 2015; Sopher et al., 2017). There is no obvious information about the thickness of UHMWPE that should be used in total ankle replacement. The optimal UHMWPE component should be strong and thin, without the risk of impairing bony strength at the bone–implant–interface (Espinosa & Klammer, 2010).

Elbow Replacement

The elbow is a complex joint consisting of three bones: Humerus is the upper part, ulna and radius are the lower parts of the hinge joint. In total elbow replacement (total elbow

arthroplasty), an artificial hinge, which is made of UHMWPE and special metal alloys, is located into the joint so all the bones can move smoothly on each other. Metal and UHMWPE hinge joints the stems together and allows the artificial joint to bend (Prkić et al., 2016). UHMWPE also minimizes the wear at the contact between the implant parts. Artificial joints come in different sizes to fit patients of different sizes.

There are mainly two types of implants: Linked types which have a mechanism linking the humeral and ulnar components and unlinked types (Sanchez-Sotelo, 2011). Both types of design rely on a metal on UHMWPE bearing couple for function (Kurtz, 2004). The unlinked elbow implants consist of two metal stems which are not mechanically jointed. The stems slide smoothly on each other and UHMWPE is used for minimizing the wear at the contact between the implant parts. Linked implants are also comprised of two metal stems which are connected with a metal locking pin. The locking pin attaches the ends of stems that are covered with UHMWPE (Bachman & Cil, 2017).

Total Disc Replacement

Total disc replacement (total artificial disc) is a surgical method in which degenerated intervertebral discs in the spinal column are replaced with artificial discs, a mobile bearing prosthesis made of metal and plastic, in the cervical (upper) or lumbar (lower) spine. Disc replacement surgery is a newer procedure that aims to preserve the intervertebral disc height of the spinal column, enhances disc flexibility, eliminates or reduces pain from motion, improves the quality of life of the patient. Total disc replacements are performed to relieve chronic low back pain caused by compressed nerves, weakness, and other symptoms due to damaged or diseased discs. They have been utilized in the lumbar spine since the late 1980s and recently in the cervical spine (Kurtz et al., 2005; Vital & Boissière, 2014). Total disc replacement devices typically include a CoCrMo alloy (Cobalt Chrome Molybdenum) socket articulating against an UHMWPE ball. Owing to its tribological properties and high chemical reaction resistance in part, UHMWPE has been commonly used as a core between the metal plates in joint disc arthroplasty as a bearing surface. There are two designs such as the Prodisc-L (Spinal Solutions) and SB Charité III (Link Spine Group) that include these components for their implant (Eckold et al., 2015). These modern devices are produced with a γ -inert-sterilized UHMWPE polymer to enhance wear performance and oxidation resistance of the cores. Wear debris is a major problem due to its effect on both implant longevity and the biological reactions that can occur in vivo as with all artificial joints (Eckold et al., 2015, Veruva et al., 2014).

SURGICAL SUTURE (NON ABSORBABLE)

UHMWPE fibers have been used in the fields of medical applications, including ligament repair, surgery and trauma of the spine, high-strength sutures, arthroscopic procedures, motion-preserving spinal applications etc. For these fibers, suture technology was one of the first applications, with the trade name of Dyneema Purity, in 2004 (Kurtz, 2009). Sutures made with UHMWPE fiber are non-absorbable which present an exciting medical bio-

engineering challenge. In the other words, it is displayed for use in ligation and/or approximation of tissue like cardiovascular surgeries and allograft tissue for orthopedic surgical procedures (Hapa et al., 2012; Kurtz, 2009).

Newer high-strength sutures comprised either partially or totally of UHMWPE demonstrate increased biomechanical properties over those of absorbable monofilament polydioxanone or nonabsorbable braided polyester suture utilized conventionally in arthroscopic repairs (Hapa et al., 2012). Sutures comprised of UHMWPE fiber were advanced to enhanced handling properties, tensile strength, limit gap formation, and decrease suture breaking. These UHMWPE sutures have submaximal resistance to slippage but certainly higher load to failure strengths than traditional braided polyester sutures (Barber et al., 2006; Barber et al., 2009). The strength of UHMWPE sutures was investigated in a porcine cadaveric model and determined that self-adjusting, UHMWPE suture-comprising meniscal repair instruments were comparable to isolated UHMWPE-containing suture repairs on load testing (Barber et al., 2006). Especially, UHMWPE sutures in equipment have further enhanced the mechanical fixation properties of meniscus repair devices. In another study, it was reported that inside meniscus repair by using UHMWPE sutures supplied greater load to failure strength than other repair techniques that utilize traditional sutures (Barber et al., 2009).

Chapter 284

NURSING CARE FOR THE SYMPTOMS OF CANCER TREATMENT

Aylin Aydin Sayilan*

Department of Nursing, Kırklareli University, Kırklareli, Turkey

ABSTRACT

Cancer is the most common disease nowadays and it has lots of side effects for patients. Nursing care for symptoms of the cancer is very important for patients. This chapter reviews the symptoms of cancer treatment and nursing care.

Symptoms of cancer include skin-related side effects, hematologic side effects, side effects related to the nervous system, respiratory system, cardiovascular system, gastrointestinal system and genitourinary system and psychoemic side effects.

Keywords: cancer, nursing care, physiological systems, symptoms

INTRODUCTION

Cancer is a complex disease caused by uncontrolled division and proliferation of cells under the influence of genetic and environmental conditions. Serious systemic side-effects are observed both in the disease period and in the treatment period; nursing care for the symptoms comes into prominence.

This article, first, discusses the side effects of the cancer and then lists what the nurses should do for the care for symptoms during the treatment period.

* Corresponding Author's Email: aylinay_85@msn.com.

SKIN RELATED SIDE EFFECTS

Alopecia

Hair loss begins 2-3 weeks after the use of the medications, the hair grows again 4-6 weeks after the end of the treatment.

Nursing Care:

- Hair loss and hair regrowth after the end of treatment should be explained to patients.
- Patients should be informed about various materials such as hats, caps, wigs, etc., which can be used to hide temporary hair loss.
- Paying attention to ensure that the material to be applied to the head should be non-irritating for the head skin.
- Short-cut hair can be suggested before chemotherapy, eye pencil, eyebrow pencil, fake eyelashes can be suggested; use of a soft brush, hair drying without using hair dryer can be suggested for the remaining hair.
- Wearing a cold weather headgear for 30 days before and after the treatment can be suggested (Kanan, 1993; Ozbas, 2003; Akdemir & Birol, 2004).

Redness of the Skin

Nursing Care:

- The patient should be informed about the possibility of skin redness, pruritus, skin drying, dermatitis and the risk of staying too long under the sun.
- The possibility of discoloration of skin and nail, the use of different colored nail polishes to hide this condition and the impermanence of this condition.
- The nails should be cut short; cotton clothes should be preferred.
- The importance of both the maintaining of hepatic enzyme control for hepatitis and daily control of the skin and sclera should be explained to the patient (Ertem et. al., 2009; Walter et. al., 2015).

Pruritus

Nursing Care:

- The skin should be dry and clean.
- Cold compresses, antihistamines and corticosteroids may be used.
- It should be explained to the patient that the skin should not be scratched to not exacerbate itching and to protect the integrity of the skin (Wu & Lacouture, 2018).

Hypersensitivity

Nursing Care:

- Urticaria, erythema, hyperpigmentation and acne-like reaction are observed within 1-3 days following the drug administration. It most commonly develops due to methotrexate, fluorouracil and doxorubicin.
- The patient avoids direct sun exposure during chemotherapy application.
- Cortisone is given as a premedication according to the request of the doctor.
- The patient is supplemented in terms of liquid.
- The patient is monitored for 2 hours after the end of chemotherapy. The patient's blood pressure is measured; adrenaline is available to be administered (Aydemir & Birol, 2004).

Extravasation

Extravasation is the penetration of vesicant chemotherapeutic agents into the subcutaneous tissues via veins.

Nursing Care:

- The procedure which is administered is explained to the patient in detail; the patient is informed that there is no pain while the medication is giving.
- The anatomic region of injection or catheterization is monitored for an abnormal symptom such as swelling, redness.
- The physiological saline solution is given into the vein rapidly. Meantime the patient is asked to say when there is any discomfort.
- Chemotherapeutic drugs, primarily vesicants are administered in accordance with the standards established by the institution.
- Medications which are suitable for the diameter of the vein are given at the recommended dose.
- The needle/catheter is frequently checked to see if it is in place.
- The pressure is monitored when drug injection is required, the operation is stopped if there is a resistance.
- The anatomic region of injection or catheterization is carefully monitored.
- The information about the drugs that cause local reactions such as erythema and urticaria was known.
- The anatomic site of injection or catheterization is constantly checked by taking into account the sensitivities which are observed at the entry site or along the vein.
- After drug infusion, 10-20 ml of physiological saline solution is given rapidly.
- If there is any doubt about the vessel patency, the infusion is stopped immediately.
- The administration of the medication is stopped, the infiltrated amount is determined, the remaining amount in the injection syringe is determined.
- The chemotherapy injector is replaced with a new injector (20 ml).

- The drug or blood remaining up to 20 mL in the IV set was attempted to aspirate.
- If the indication is known, the antidote is slowly administered through the needle or catheter (IV).
- If it is not possible to aspirate the vesicant drug from the set, the needle is removed. Local ethyl chloride is applied to this numb region; the antidote is injected subcutaneously with a 25-gauge syringe.
- Bandages are applied without pressing on the affected area. The extravasation site is immobilized and the arm is held high for three days. It is regularly monitored in terms of pain, erythema and stiffness.
- If the pain still persists after 72 hours, a plastic surgery consultation may be needed (Chanes et al., 2012).

Skin Irritation

The aim of care in skin irritation is to minimize the skin reactions by assessing the site of the treatment and to maintain the integrity of the skin to prevent the development of infection.

Nursing Care:

- Keeping the area clean and dry.
- Not rubbing and scratching the treatment region.
- Lightly washing the area with warm water and non-perfumed soft soap, drying with a soft towel.
- Not using talc powder, lotion or deodorant because they increase irritation.
- Wearing sweat absorbing, soft and abundant clothes, wearing long sleeved dress to protect the region from extreme heat and cold, direct sunlight, wearing wide-edge hats and using sun screen creams are important (Tuna 2014).

HEMATOLOGICAL SIDE AFFECTS

Anemia

The aim is to monitor signs of anemia, to detect them early and to take necessary precautions.

Nursing Interventions:

- Anemia signs such as fatigue, dizziness, trembling or tachypnea should be monitored.
- If orthostatic hypotension dizziness is observed, the patient should be informed to move slowly, especially when lying down and getting up.
- Hemoglobin and hematocrit should be monitored at regular intervals.
- The patient may need blood transfusion and erythropoietin according to the request of the doctor (Sabol et. al., 2010).

Neutropenia

- The signs of infection (fever, redness, temperature, edema, pain, inflammation, etc.) should be monitored.
- The sites where infection is mostly observed such as skin and mucous membranes, oral cavity, respiratory system and urinary system should be monitored; patient's oral and body hygiene should be attached importance and be performed daily, the skin should be protected from trauma.
- Perianal region should be cleaned with warm water and soft soap.
- Nails are cut short and straight.
- Skin integrity should be protected; skin should be cleaned Daily.
- The patient, his/her family and health personnel should take care to wash hands.
- The rest and nutrition of the patients should be cared (Vioral & Wentley, 2015).

Thrombocytopenia

The aim is to observe and to detect bleeding signs early, to prevent trauma related bleeding, to assess bleeding and to control bleeding.

- The blood count of the patient, especially the platelet level should be monitored.
- The platelet count should be kept above 20000.
- Patients should be protected from trauma.
- Soft materials should be used for oral care.
- Aspirin and non-steroid anti-inflammatory drugs should not be used.
- IM injections should be avoided; if necessary, pressure should be applied for 3-5 minutes after the procedure.
- Skin should be evaluated for petechial-ecchymosis.
- Unusual bleedings should be reported.
- If necessary, blood or platelet transfusion should be performed according to the physician's request (Esencan & Merih, 2010).

NERVOUS SYSTEM RELATED SIDE EFFECTS

Cerebral Edema

It is important to diagnose the symptoms of cerebral edema in the treatment of primary brain tumors or brain metastases by radiotherapy. These symptoms are considered as headache, nausea, vomiting, visual disturbances, inadequacy in motor function, and changes in mental status. It is stated that regular monitoring of the life signs of the patient with cerebral edema, the application of the planned treatment in the direction of the physician's request, frequent controls of the patient's level of consciousness are important (Jha, 2003).

RESPIRATORY SYSTEM RELATED SIDE EFFECTS

Radiation Pneumonia

It is known that the possibility of the development of radiation pneumonia is high 1-3 weeks after the radiotherapy administered to lungs. It is emphasized that the presence of signs of fever and dyspnea indicates pneumonia in patients. Nursing interventions applied in patient care include administering steroids and antibiotics according to the physician's request and ensuring bed rest of the patient in addition to the interventions applied the patient with a coughing problem (Yılmaz et. al., 2014).

Radiation Fibrosis

It is stated that treatment related radiation fibrosis 6-12 weeks after the completion of radiotherapy is a restrictive pulmonary disease. The determination of dyspnea as the first symptom and the application of nursing interventions related to it have been addressed (Giridhar et. al., 2015).

Coughing

It is important to define the frequency, severity and characteristics of coughing that develops as a side effect of radiotherapy. The aim of care is to provide an effective open airway and to prevent both the deterioration of airway functions and the development of infection.

Nursing Interventions:

- Positioning the patient with the purpose of ensuring and maintaining airway patency.
- The application of respiratory exercises.
- Providing oral care frequently.
- Frequent ventilation of the room.
- Giving training to patients to prevent the use of irritant substances such as cigarettes that exacerbate coughing (Harle et. al., 2012; Molassiotis et. al., 2017).

CARDIOVASCULAR SYSTEM RELATED SIDE EFFECTS

Cardiotoxicity

- It may develop in the patient depending on the use of doxorubicin. If the patient takes the medication with a total dose of $<550 \text{ mg/m}^2$, the incidence of cardiomyopathy is 0.5%. But, if the patient takes the medication with a total dose of $>600 \text{ mg/m}^2$, the incidence of cardiomyopathy increases up to 30%.

- Changes in ECG such as tachycardia, extrasystoles, changes in ST-T waves were observed within the first week of drug administration. Rhythm changes are reversible. Congestive heart failure becomes chronic if it results in chronic cardiomyopathy.
- Doxorubicin should be limited to the dose of 450 mg/m².
- Congestive heart failure should be treated by using diuretics, digoxin and other cardiotonic drugs (Vasiliadis et. al., 2014).

GASTROINTESTINAL SYSTEM RELATED SIDE EFFECTS

Stomatitis

It usually develops 7-14 days after the administration of the chemotherapeutic agent. Doxorubicin causes reduction in saliva production. Oral epithelial exfoliation occurs. Oral cavity erythema edema, mouth dryness, lips irritation, tongue edema or infection, superficial inflammation that may cause white irregular spots, fever blister like lesions are observed.

Nursing Care:

- Good oral hygiene is provided before and during chemotherapy.
- Oral cavity is checked and evaluated every day.
- Appropriate oral care is taught to the patient.
- If there is no lesion, the teeth are brushed with a soft toothbrush in 4 hours, mucostatin and betadine are used to gargle.
- If there is a lesion, oral care is carried out with hydrogen peroxide solution every two hours, it is followed by oral care with physiological saline solution, after that Vaseline is applied on the lips.
- Fluid balance is maintained.
- It is recommended to avoid from acidic, spicy, minty, salty and savory foods.
- If the lips are dry, they are softened with Vaseline or vitamin E preparations (Farrington et. al., 2013; Araújo et. al., 2015).

Diarrhea

The aim is to prevent diarrhea, to meet the needs of the body with an adequate and balanced diet and to maintain normal weight.

Nursing Care:

- The daily number of defecations and the characteristics of defecations are identified and recorded.
- Intestinal habits are defined.
- The fluid intake of the patient is monitored, lost fluid is replaced.
- The number of feces is recorded and each feces is assessed in terms of bleeding.

- Low fibrous foods, cooked foods are included in the menu.
- Milk products are avoided; if there is no objection, banana, orange, potatoes are given to compensate loss of potassium.
- The amount of fat in the diet is reduced.
- Patients should sparingly and frequently eat foods having low sugar content which are not too hot or not too cold (Shaw & Taylor, 2012).

Constipation

It is quite common because of the opioids used for the control of pain. 50% of cancer patients experience constipation, 78% of these patients are terminal-stage cancer patients.

Nursing Care:

- Fibrous foods are recommended (vegetables, fruits, oats, etc.).
- Fluid intake increase (at least 2lt per day).
- Physical activity is recommended.
- When non-pharmacological practices are not beneficial, laxatives may be given to the patient according to the physician's request, but enema application may be objectionable in these patients (Yu & Ko, 2010).

Nausea-Vomiting

Nausea and vomiting usually occur within the first 6 hours after the treatment. The aim of the care is to maintain fluid and electrolyte balance, to provide adequate nutrition and to protect the oral mucosa.

Nursing Interventions:

- It is important to evaluate and record vomited material in terms of quantity, content and color.
- It is important to administer antiemetic drugs at least half an hour before meals and the administration of chemotherapeutic drugs.
- It is important to provide oral care frequently.
- It is important to monitor body weight, fluid intake and fluid output and electrolyte values.
- The patient's methods to cope with nausea-vomiting are found out.
- The physical environment is kept clean and odorless; the clothes of the patient are ensured to be comfortable.
- Before and during the treatment, a cold pad is placed on the eyes of the patient; liquid and food restriction is done 4-6 hours before the treatment.
- It is suggested that the patient eat gradually and frequently, chew well, and avoid taking liquid at meals (Haugland & DeVon, 2018).

Anorexia

There is an unwillingness to eat and as a result of that the body weight decreases in time.

Nursing Interventions:

- Nurses should plan the nutrition program of the patient in cooperation with a dietitian.
- Nurses should encourage the patient to eat high calorie and protein foods.
- Nurses should recommend to eat gradually and frequently.
- Nurses should recommend to perform oral care after each meal.
- Nurses should eliminate unpleasant odors or odors that the patient does not like.
- Nurses should maintain feeding via enteral nutrition or intravenous nutrition when the patient cannot feed orally (Berry et. al., 2018).

Hepatotoxicity

Prolonged use of methotrexate causes damage to the liver. Preexisting liver disease increases the risk. Hepatic fibrosis, hepatitis and an increase in liver enzymes are observed in the patient. The patient's liver function tests should be checked before chemotherapy begins (Cai et al., 2014).

Dryness of the Mouth

Saliva production decreases as a result of the effect of radiotherapy on salivary gland and therefore dryness of the mouth may occur.

Nursing Interventions:

- Informing the patients and their families.
- Emphasizing the importance of oral care.
- Encouraging the patient to eat juicy foods with meals.
- Giving advice to the patient to avoid from the foods containing lemon, glycerin and alcohol.
- Using commercial solutions to eliminate dryness of the mouth.
- Humidifying the patient's room.
- Encouraging the patient to intake plenty of fluid (Riley et. al., 2017).

Orthodontic Problems and Tooth Decay

It is stated that orthodontic problems and tooth decay are widespread as a result of dryness of the mouth in the patients who are treated with radiotherapy.

Nursing Interventions:

- Nurses should emphasize the importance of dental examination of the patient by a dentist before the treatment.
- Nurses should give a training on daily fluoride applications on teeth.
- Nurses should restrict the fluid intake for at least 30 minutes after fluoride applications (Gallarreta et al., 2013).

Osteoradionecrosis

Osteoradionecrosis is considered as a late and chronic side effect of radiotherapy, is known to be a side effect that can occur in situations in which jaw bone structure is affected as a result of both tooth decay and infection. In the literature, it is stated that hyperbaric oxygen therapy may play a role in the healing of the bone as well as antibiotic applications in the treatment of osteoradionecrosis.

Nursing Interventions:

- Maintenance and support of oral care.
- Guidance for regular dental examinations.
- Monitoring of the suitability and comfort of dental prostheses.
- Informing the patient to decrease oral irritations caused by the use of substances such as cigarettes/alcohol comprise the goals of the nursing care (Firdoose & Hasoon, 2018).

Esophagitis

Esophagitis is seen during radiotherapy applications involving the esophagus region. The patient may report a pain/difficulty during swallowing and swelling in the throat. It is emphasized that it may be serious enough to prevent the practice of radiotherapy.

The intake of sweet, soft and liquid nutrients containing high amount of calorie and protein should be controlled in the diet of the patient. It should also be kept in mind that analgesics given 1-2 hours before meals may be effective in relieving pain and in maintaining nutrition of the patient (Etiz et al., 2013).

GENITOURINARY SYSTEM RELATED SIDE EFFECTS**Renal Toxicity**

It occurs secondarily due to the collapse of the renal tubules. It most commonly occurs due to methotrexate.

Nursing Interventions:

- Fluid balance is maintained.
- Blood urea nitrogen (BUN), serum creatinine levels are checked.
- Creatinine clearance is measured.
- Uric acid and electrolytes in blood serum are analyzed and evaluated (Lydon, 1989; Mallick et. al., 2015).

Cystitis

It is reported that cystitis seen as a result of bladder radiotherapy, appears with thrombocytopenia, a decrease in bladder capacity and nocturia. In the literature, it has been stated that hyperbaric oxygen therapy improves the oxygenation of the tissues by providing granulation tissue formation and vascular growth; it is useful in the treatment of cystitis depending on radiotherapy.

Nursing Interventions:

- Fluid balance is maintained.
- BUN, serum creatinine levels are checked.
- The creatinine clearance is measured.
- Uric acid and electrolytes in blood serum are analyzed and evaluated (Lydon, 1989; Mallick et. al., 2015).

PSYCHOEMOTIONAL SIDE EFFECTS**Fatigue**

Fatigue is one of the most common problems in cancer patients and is related with the factors such as nausea, vomiting, diarrhea, pain, immobility, anemia and malnutrition.

Nursing Care:

- The care needs of the patient should be fulfilled in a short time.
- Selecting light exercises according to the type of the treatment may help increase the energy level of the patient.
- It is ensured that patients do important activities when they have a high energy level, but they do not do these activities in a way that cause them to feel more fatigued afterwards; patients are ensured to get adequate amount of nutrition according to the Daily Living Activities Scale (DLA).
- It is recommended to drink at least 8-10 glasses of water per day in order to be able to remove collapsed cells and residual products (Mitchell et. al., 2014).

Pain

According to the suggestion of the WHO

- Non-narcotic analgesics + adjuvant therapy (aspirin, paracetamol) for mild pain.
- Poor narcotics + nonopioid-adjuvant therapy (tolvin, dihydrocodeine, demoral) for moderate pain.
- Strong narcotics + nonopioid drugs + adjuvant therapy (morphine) for severe pain.

Nonpharmacological applications recommended for pain control include position change, massage, warm or cold application, warm baths, providing a quiet and calm environment, teaching relaxation techniques, radio, television, reading, listening to music and dreaming (Yamanaka, 2018).

Anxiety and Depression

The symptoms such as stress, restlessness, headache and anorexia can be seen in the patient due to the remission (relief of symptoms of the disease), relapse (recurrence) and exacerbation (exacerbation) periods in chemotherapy.

Nursing Care:

- Positive communication and cooperation with the patient and his/her family should be maintained.
- If the patient feels a loss of control, his/her control should be restored or the patient should be ensured to feel that he/she controls his/her environment; this situation encourages the patient to struggle against difficulties.
- Sufficient psychosocial support should be provided to the patient and his/her family.
- For this reason, social counselors should be in the oncology centers.
- Physicians, nurses and other health professionals who are interested in oncology should be raised awareness on psychosocial oncology.
- The social services needed by the patient and his/her family should be determined.
- When giving information about the diagnosis and treatment, the patient should be informed with clear and understandable information (Yoo et. al., 2009; Tsaras et. al., 2018).

Chapter 285

MORTALITY AND LIFE EXPECTANCY IN POST-COMMUNIST COUNTRIES: WHAT ARE THE LESSONS FOR OTHER COUNTRIES?

Vladimir Popov*

Dialogue of Civilizations Research Institute,
Berlin, Germany

INTRODUCTION

The transition to the market economy and democracy in Eastern Europe and former Soviet Union countries in the 1990s caused a dramatic increase in mortality, shortened life expectancy, and led to depopulation. In Eastern European countries (including East Germany), in most cases life expectancy fell by 2-3 years at the beginning of the 1990s; the most pronounced decline was observed for men in their 40s and 50s. In Russia, the steep upsurge in mortality and the decline in life expectancy were the biggest ever recorded anywhere in peacetime and in the absence of physical catastrophes, such as wars, plague, or famine. This type of natural experiment provides rich material for understanding the impact that different types of social upheavals and stresses have on mortality and life expectancy.

There have been numerous studies and explanations of the increase in mortality (e.g., stress associated with the transition to the market economy and privatisation; alcoholism, economic hardship, and the ‘demographic echo’), but there is still no agreement among scholars as to the most important drivers of the mortality crisis in post-communist countries during transition.

This book compares different explanations and to summarises ‘state of the art’ research on the mortality crisis in post-communist countries. This crisis is also compared with other major cases of known decline in life expectancy due to social, ‘non-material’ reasons (e.g., the transition from the Palaeolithic to the Neolithic age; the enclosure movement and the industrial revolution in Britain over the course of the 16th and 18th Centuries; the aftermath

* Corresponding Author’s Email: VPopov@doc-research.org.

of the abolition of slavery and the civil war in the US; and the recent rise in mortality among the non-Hispanic white population in the US since 1999, to name but a few) in order to draw out lessons about the type of stress shocks that can lead to an increase in mortality.

STYLISTED FACTS

Dramatic increases in mortality rates and a shortening of life expectancy were a truly unprecedented, unexpected, and still little-discussed phenomenon, leading to depopulation throughout the entire region of Eastern Europe (EE) and the former Soviet Union (FSU) during the transition to the market economy and democracy in the 1990s. In fact, the steep upsurge in mortality and decline in life expectancy in the FSU and EE states were the greatest ever recorded anywhere in peacetime and in the absence of catastrophes like wars, epidemics, natural disasters, or famine.

This unique part of the transition story, which does not have analogues in other countries, was associated with comprehensive market-type reforms which added an additional shock to the shock of democratisation. Deregulation of prices and ensuing changes in relative prices led to mass reallocation of capital and labour, and hence greatly contributed to stress factors like increased unemployment, migration, labour turnover, divorce, and income inequalities. However, generally, countries with stronger institutions, either democratic (like EE), or authoritarian (like China and Vietnam), managed to cope with stress factors better than others. Furthermore, only authoritarian regimes (China is the primary example) were able to choose and implement a strategy of gradual transition which allowed a stretching out of the required restructuring – the reallocation of capital and labour – over a considerable period of time and thus mitigated the stress associated with unemployment, migration, and labour turnover (Popov, 2007).

Generally, countries which proceeded with more gradual reforms (e.g., China, Uzbekistan, and Belarus) also managed to preserve institutional capacity and either to avoid completely, or at least to mitigate, a collapse of output and the increase in mortality (Popov, 2000; Popov, 2007). The decline in life expectancy in Belarus, for example, from 72 years to 68 compared favourably against a decline from nearly 70 years to 64 in Russia (Figure 1).

China and Vietnam did not experience a transformational recession during transition and life expectancy in these countries grew steadily – although in China this occurred very slowly in comparison with the rise in life expectancy during Mao's rule (life expectancy increased from 35 to 65 years between 1949 and 1976) and in comparison with other countries with similar levels of GDP per capita and similar expectations for life expectancy. Besides, in countries with strong institutions, there was at least one case (Cuba), where the reduction of output (about 40% across the 1989-94 period) did not translate into a mortality crisis. Life expectancy in Cuba increased from 75 years in the late 1980s to 78 years in 2007.

In Russia, the increase in mortality was especially pronounced. The mortality rate increased by 60%, from 1.0% to 1.6%, whereas life expectancy fell from 70 in 1987 to 64 in 1994 (Figure 1). In fact, mortality increased to levels never observed from the 1950s to the 1980s, i.e., for a period of at least 40 years. One has to go as far back as 1940 to find mortality rates higher than in the 1995-2005 period (data for the 1941-49 period – representing World War Two and post-war reconstruction – are missing).

Figure 1. Mortality rate (per 1000, left scale) and average life expectancy (years, right scale).

The increase in mortality in Russia occurred across two periods: an initial mortality hike with a peak in 1994, with a subsequent decline, and a later increase in mortality after the 1998 financial crisis up until 2003 (see Figure 1). The rise in mortality after the August 1998 crisis (1998-2003) went hand in hand with growing output, but with fluctuating (i.e., growing and declining) unemployment rates, so at least one of the stress factors was not contributing to the new upsurge in mortality. However, the sharp decline in real incomes that occurred after the August 1998 crisis could have become a major stress factor in itself, even though its direct impact (via a deterioration of nutrition) on mortality could have been limited. Besides, income inequalities, labour turnover, migration indicators, and the divorce rate did not show any signs of decline after the 1998 crisis and before 2002-03. After 2002-03, unemployment continued to decline and the divorce rate also began to fall.

It is also noteworthy that there was no decline in life expectancy during the 2008-09 recession in Russia (Belarus and Poland were the only two European economies which avoided the 'great recession'), although the reduction of output and real incomes was significant – over 10% from a peak to a trough, from the highest month to the lowest month, and the unemployment rate increased from 5.4% in May 2008 to 9.4% in February 2009. Perhaps, over the last two decades of transition, people have already adjusted to stress (and those who have failed to adjust have died out), such that economic downturns are no longer associated with an increase in mortality.

There is, therefore, an even more compelling reason to consider the 1990-2003 fall in life expectancy as an exceptional development.

The increase in mortality rates in post-communist states has a few parallels in history. One is the transition from the Palaeolithic to the Neolithic age from about 7,000 to 3,000 BC, when life expectancy fell by several years – possibly due to changes in diet and lifestyle (i.e., the transition from hunting and gathering to horticulture and husbandry). Another comparable case is the increase in mortality during the time of Britain's Enclosure Acts and Industrial Revolution from the 16th to the 18th Century, when life expectancy fell by approximately 10 years (from about 40 years to slightly over 30 years) because of changes in lifestyle, increases

in income inequalities, and the impoverishment of the masses (Figure 2). Cases of reduced life expectancy due to social changes are rare and do not involve a fall in life expectancy by six years for the entire population of a large state (Cornia, 2004).

A recent stagnation (and even decline in 2015-16) in life expectancy has occurred in the US: a fall of 0.1 years from 2014 to 2015, and then of another 0.1 years from 2015 to 2016. Among OECD countries, the US experienced the second smallest overall increase in Health-Adjusted Life Expectancy (HALE) between 2000 and 2015, just 1.9 years, whereas more than half of the other OECD countries enjoyed an increase of more than 3 years (Sachs, 2018).

Moreover, there has been a rise in age-adjusted mortality for the white non-Hispanic working age population – a very rare phenomenon in a high-income country (Squires and Blumenthal, 2017). Case and Deaton (2015) document a marked increase in the mortality of middle-aged white non-Hispanics in the US after 1998 in all 5-year age groups from 30 to 55. The leading immediate causes for increased mortality were poisoning, suicide, chronic liver disease, and cirrhosis. Increasing mortality for the middle-aged white population was matched by increasing morbidity. When seen side by side with the mortality increase, declines in self-reported health and mental health, increased reports of pain, and greater difficulties with daily living show increasing distress among the white midlife population after the late 1990s.

Source: Data from Wringley and Schofield (1981); figure by the present author.

Figure 2. Mortality rates and life expectancy (at birth) in the course of early urbanisation in England, 1540-1870.

Sachs (2018) points out three major reasons: obesity, drug use, and depression. The latter can be caused by stress due to a loss of social status, social dynamism, and life perspective. The relative position of the non-Hispanic white population in recent decades declined more than any other segment of the population.

“Although the epidemic of pain, suicide, and drug overdoses preceded the financial crisis, ties to economic insecurity are possible. After the productivity slowdown in the early 1970s, and with widening income inequality, many of the baby-boom generation are the first to find, in midlife, that they will not be better off than were their parents. Growth in real median

earnings has been slow for this group, especially those with only a high school education. However, the productivity slowdown is common to many rich countries, some of which have seen even slower growth in median earnings than the United States, yet none have had the same mortality experience.... The United States has moved primarily to defined-contribution pension plans with associated stock market risk, whereas, in Europe, defined-benefit pensions are still the norm. Future financial insecurity may weigh more heavily on US workers, if they perceive stock market risk harder to manage than earnings risk, or if they have contributed inadequately to defined-contribution plans” (Case and Deaton, 2015).

LITERATURE REVIEW

What caused an increase in mortality during transition? Of course, there was a transformational recession in the 1990s; crime, murder, and suicide rates sharply increased as well. However, the staggering increase in mortality that occurred during transition (most pronounced for middle-aged men and mostly caused by cardiovascular diseases) cannot be fully explained by ‘material’ factors like falls in real incomes leading to poor nutrition, deterioration in the quality of the environment and health care system, alcoholism, and smoking (Shapiro, 1995; Leon, Chenet, Shkolnikov, Zakharov, Shapiro, Rakhmanova, Vassin, and McKee, 1997). It has been pointed out that a change in diet (from meat and milk products to bread and potatoes) would not have been able to cause an increase in cardiovascular diseases. Furthermore, emissions of pollutants actually decreased with the collapse of industrial output, and a major impact in terms of deteriorating health care, smoking, and alcoholism (as well as changes in diet) should only result in increased mortality with a lag of several years, but this was evidently not the case (Cornia, 1997; Cornia and Panizza, 2000).

The upsurge in mortality also cannot be explained by the ‘demographic echo’ theory – that the increase in mortality in 1989-94 was merely an echo of the decrease that occurred during Gorbachev’s anti-alcohol campaign in 1985-87 (Avdeev, Blum, Zakharov, and Andreev, 1998). The echo, in this case, seems to be several times larger than the initial shock.

Whereas most experts would agree that the deterioration of the diet and the deterioration of the health care system, as well as increases in deaths from external causes (accidents, murders, suicides), contributed to the general increase in mortality in Russia and many other post-communist countries, they would not, for the most part, regard them as primary factors. Today, there seem to be two major competing theories: One states that the transition mortality crisis is generated by stress factors; another attributes the rise in mortality to alcohol consumption.

Stress factors are associated with the transition to the market economy, driven by rises in unemployment, labour mobility, migration, divorce, and income inequalities (Cornia, 1997; Cornia and Panizza, 2000). It has been found that a stress index constructed out of the aforementioned variables serves as a good predictor of changes in life expectancy in post-communist economies. Men in their 40s and 50s who either lost their jobs (or had to move to another job or another region); or whose country or region encountered increased inequality; or who divorced their wives, were the first candidates to die prematurely in the 1990s (Cornia and Panizza, 2000). The mortality crisis has revealed, like nothing before, the role of social stress on life expectancy. In a sense, this was a natural experiment of a kind that happens only

once every thousand years, and it has shown how much stress a society can take without dying out. Accordingly, King, Stuckler, and Hamm (2006) argued that mass privatisation programmes created psychological stress which directly resulted in higher mortality.

The major theory that competes today with the stress-related explanation of the upsurge in mortality is the increase in alcoholism (Leon, Chenet, Shkolnikov, Zakharov, Shapiro, Rakhmanova, Vassin, and McKee, 1997; Vishnevsky and Shkol'nykov, 1999; Pridemore, 2008). An increase in alcohol consumption only occurred in the early 1990s (see Figure 3). At first glance, it does appear that alcohol consumption is closely related to deaths from external causes (murders, suicides, and accidents) as well as to the general mortality rate (Squires and Blumenthal, 2017). Death rates per 100,000 inhabitants due to alcohol poisoning increased from 10 in 1990-91 to nearly 40 in 1994, exceeding the number of deaths due to suicide and murder (Figure 3).

Stress, of course, is related to alcoholism and may, in fact, be the major cause of it (see, for example, Dawson, Grant, and Ruan, 2005; Childs, O'Connor, and de Wit 2011), so it is difficult to separate these two hypotheses. But stress can cause increased mortality even without an increase in alcoholism, whereas an increase in the consumption of alcoholic beverages can occur without stress. In the Russian case, an increased intake of alcohol can be attributed to a decline in the relative prices of spirits in the early 1990s.

Treisman (2010) argues that the surge in alcohol-related deaths – and premature deaths in general – was fuelled by a dramatic fall in the real price of vodka, which dropped 77% between December 1990 and December 1994. Variation in vodka prices – both over time and across Russia's regions – closely matches variation in mortality. Although market competition and weak excise collection help explain the fall in prices, the main reason appears to be populist price regulation during inflationary periods. Bhattacharya, Gathmann and Miller (2013) use an oblast-year [1] dataset spanning 1978–2000 and find a variety of evidence suggesting that the end of Gorbachev's anti-alcohol campaign explains the mortality crisis to a significant extent, whereas Russia's transition to capitalism and democracy was not as lethal as sometimes suggested.

The increase in consumption of alcohol really occurred in the early 1990s, according to official data, and even in the late 1980s – during the anti-alcohol campaign – according to unofficial estimates (Figure 4). Deaths from alcohol poisoning are often regarded as better indicators of alcohol consumption (because some alcohol is produced illegally and smuggled). Deaths per 100,000 inhabitants increased from 10 in 1990-91 to nearly 40 in 1994 and exceeded the number of deaths due to suicide and murders (Figure 3). Later, however, by 2007, the rate of these alcohol-related deaths fell to late Soviet levels, even though total mortality rate remained considerably above late/Soviet levels (Figures 1, 4). The increase in the intake of alcohol, in turn, is attributed to the decline in relative prices of spirits in the early 1990s. It has been shown that the demand for alcohol, like the demand for other goods, is negatively affected by price and positively affected by personal income (Andrienko and Nemtsov, 2006).

Nemtsov (2002) attributes as much as one-third of total deaths in Russia to alcohol-related causes (including indirect causes), which is much higher than official estimates (less than 4% deaths from causes directly related to alcohol consumption), a view widely held by Western experts: "Despite the improving situation, one-third of all deaths in Russia are directly or indirectly related to alcohol, requiring intervention at a variety of levels" (Pridemore, 2008). Many experts consider these estimates exaggerated. Official statistics

report that only 3% of all deaths are caused by alcohol (alcohol poisoning, liver cirrhosis, alcoholism, and alcoholic psychosis). Anatoly Vishnevsky (in personal communications) attributes about 12% of all deaths to alcohol-related causes [2].

Source: For death rates, WHO database and Goskomstat; for legal sales of alcohol, Goskomstat; for alternative estimates of alcohol consumption, Demoscope, No. 263-264, Oct. 30–Nov. 12, 2006.

Figure 3. Sales of alcohol, litres of pure alcohol per capita (left scale); death rates per 100,000 from alcohol poisoning, murders, and suicides (right scale).

It seems obvious that increased alcohol consumption contributed to the rise of deaths due to external causes – accidents, murders, suicides (Figure 4). In 2002, the death rates from external causes in Russia was not among the highest, but were the highest in the world. There is also an apparent correlation between alcohol consumption and deaths from all causes, but this does not necessarily imply causation.

Firstly, there is controversy over the impact of increases in the intake of alcohol on cardio-vascular diseases. A recent (Arriola et al., 2009) 10-year survey of 41,000 people aged 29-69 found that, compared with male non-drinkers, those that drank before but later quit drinking have a 10%-lower chance of heart problems; those that drink small amounts (less than 0.5 grams per day) have a 35%-lower chance; those that drink moderately (5-30 grams per day) have a 54%-lower chance; and big drinkers (30-90 grams per day) and alcoholics (more than 90 grams per day) have a 50%-lower chance of heart problems.

Secondly, there are some periods when per capita alcohol consumption and death rates moved in opposite directions – in 2002-07, deaths from external causes, including murders, suicides, and poisoning, fell alongside rising alcohol consumption (Figure 5). Similar inconsistencies exist for the 1960s: From 1960 to 1970, alcohol consumption increased from 4.6 to 8.5 litres per capita, according to official statistics, (and from 9.8 to 12 litres according

to alternative estimates), whereas life expectancy did not change much: 69 years in 1960; 70 in 1965; 69 in 1970.

Source: Goskomstat.

Figure 4. Mortality and alcohol consumption.

And thirdly, levels of per capita alcohol consumption in the 1990s, according to both official statistics and alternative estimates, were equal to or lower than in the early 1980s, whereas deaths from external causes doubled and the total death rate increased by 50% (compare Figures 1 and 3). It appears, therefore, that we can observe a simultaneous increase in variables (total death rate and deaths from external causes, as well as alcohol consumption) that are all driven by another factor, which is very likely stress.

Grigoriev and Andreev (2015) show that in the 1980–2013 period only a limited number of causes of death for the male population can be attributed to alcohol-related reasons: accidental poisoning by alcohol; liver cirrhosis; ischemic heart diseases; stroke; transportation accidents; and other external causes. They argue that a continuous reduction in adult male mortality seen in Belarus and Russia cannot be fully explained by the anti-alcohol policies implemented in these countries, although these policies likely contributed to the large mortality reductions observed in Russia in 2005–2006 and in Belarus in 2012. Anti-alcohol measures implemented in Belarus and Russia simply coincided with fluctuations in alcohol-related mortality, which had their origins in the past. If these trends had not been underway already, these huge mortality effects would not have occurred.

The counterargument is that it is not the consumption of all alcohol, but of hard spirits, vodka, in particular, that should be blamed for the increase in mortality. It is noteworthy that the consumption of vodka in Russia has fallen sharply in recent years (from over 200 million dekalitres in the early 1980s and in the 1990s to about 100 million in 2015), whereas the share of wine and beer in total alcohol consumption increased markedly (Figure 5).

Finally, there is a view that the stress of the transition to the market economy causes both a rise in mortality and an increase in alcohol consumption, such that both phenomena go hand in hand, but do not necessarily cause one another. Popov (2010) shows that vodka

consumption itself was strongly correlated with stress factors in Russian regions. The most successfully performing regions, such as resource-rich regions, were relatively worse off in terms of stress factors, leading to greater increases in mortality, greater increases in vodka consumption, and greater reductions in life expectancy (Popov, 2010; Walberg, 1998).

Source: Goskomstat.

Figure 5. Retail sales of vodka and all alcohol alongside life expectancy.

Cross-country and cross-regional regressions of changes in life expectancy and mortality in relation to stress factors and alcoholism do not shed light on the true impact of these variables, due to the high level of multicollinearity between them; so it is necessary to examine individual life histories in order to understand what the contribution of various factors is. One such study, by Denisova (2010), is based on twelve rounds of the Russian Longitudinal Monitoring Survey of households spanning the 14-year period from 1994 to 2007. 1,245 adults (5% of the adults in the sample) died, with 546 deaths in the 18-65 age group (3% of the adults of the age group). It was found that relative status measured in non-income terms, labour market behaviour, sectoral and occupational mobility, and smoking and alcohol consumption have a strong effect on longevity, but there is no evidence that the low relative price of vodka led to greater alcohol consumption.

A recent project on the impact of privatisation on mortality and life expectancy (Irdam, 2016; Azarova, 2017; PRIVMORT, 2017) used micro-level data with enterprise and settlement-level data to enable a comprehensive analysis of both distal and proximal causes of mortality. It was based on an extensive survey of households in Belarus, Hungary, and Russia[3] and found that privatisation, and especially fast privatisation, even after controlling for alcoholism, smoking, age, marital status, and financial deprivation, increase mortality significantly (Irdam et al., 2016; Azarova et al., 2017).

PUZZLES AND HYPOTHESES

How do changes in living standards affect life expectancy? The impact is often counterintuitive – that is, the fall in material wellbeing leads to a rise in life expectancy. It is well known, for example, that during the Great Depression in the US life expectancy rose considerably (faster than the previous trend suggested) – from 57.1 years in 1929 to 63.3 years in 1932; the increase occurred for both men and women, and for both the white and non-white populations; mortality rates from all causes of death, except for suicides, fell (Granados, Roux, 2009).

During the 1998 Asian currency crisis, the fall in GDP in many countries was accompanied by a fall in mortality (Figure 6); but in Russia, Belarus, Ukraine, and other economies in transition, transformational recession has resulted in an increase in mortality rates.

Recent research on the link between mortality rates and economic conditions has identified a pro-cyclical relationship. Ruhm (2000), who uses state-level data for the US and a fixed-effect model, shows that a fall in the unemployment rate leads to a sustained rise in the mortality rate. Except for suicides and deaths from cancer, this pro-cyclicality between unemployment and the mortality rate is robust for ten other causes of mortality, especially for motor-vehicle accidents and heart diseases. Gerdtham and Ruhm, (2006) find similar evidence for OECD countries.

Other researchers, however, have found a negative impact of recessions on mortality in developing countries and even in developed countries too, for particular groups. For example, Reichmuth and Sarferaz (2008) show that young adults in France, Japan, and the US exhibit increased mortality in a recession, whereas most of the other age cohorts between childhood and old age react to increased unemployment or decreased GDP growth with lower mortality rates. Using individual data records from Dutch registers for birth, marriage, and death certificates, covering the period 1815-2000, Van den Berg, Lindeboom and López (2006) demonstrate that recessions have an adverse impact on mortality, although not immediately, but rather later in life, due to lower levels of nutrition in early life. Being born in a recession increases mortality rates later in life for most of the population and especially for poorer social classes. Based on social security data for the US, Sullivan and von Wachter (2009) estimate that a higher mortality rate due to unemployment persists up to 20 years after the job loss and leads to an average loss of life expectancy of 1-1.5 years.

There is also evidence that in developing countries, unlike developed countries, recessions have a strong adverse effect on social indicators, including life expectancy and infant mortality. Conceição and Kim (2009) find that life expectancy for a sample of over 200

countries falls by an average of over four years during episodes of growth deceleration (defined roughly as three or more years of falling output) as compared to periods of rapid growth, whereas infant mortality and mortality for the under-5 age group nearly doubles.

Figure 6. Mortality rates in Thailand, Russia, and Ukraine.

Among all causes of death, only one – suicide – always seems to be correlated with economic conditions (unemployment). During the Great Depression, for example, the suicide rate in the US increased by about 20% from 14 to 17 suicides per 100,000 people. The Asian economic crisis in 1997 led to an estimated 10,400 additional suicides in Japan, Hong Kong, and South Korea, with suicides spiking more than 40% among some demographic groups. The unemployed commit suicide at a rate two or three times the national average, researchers estimate. And in many cases, the longer the spell of unemployment, the higher the likelihood of suicide. Suicide prevention hotlines also showed signs of stress in the recent ‘great recession’. In January 2007, as the recession began, there were 13,423 calls to the National Suicide Prevention Lifeline, a toll-free nationwide hotline. A year later, there were 39,467. In August 2009, the call volume peaked at 57,625 (Huffington Post, 2017).

What remains to be figured out is why recessions in some instances (when output falls and unemployment rises) do not lead to a general increase in mortality, whereas in other cases recessions cause a marked increase in mortality.

Another puzzle is the stagnation of life expectancy in Russia for the 20 years between 1965 and 1985 and the rapid recovery of life expectancy after the transition’s mortality crisis. In Russia, after diverging with developed countries in the period of social stagnation (1970-80s) and decline (1990s), life expectancy is rapidly rising again (Figure 7). In 2016, it reached 72 years – the highest level ever.

Source: WDI database.

Figure 7. Life expectancy at birth in Russia and the US, 1966-2013, total (years).

It remains to be seen whether this growth of life expectancy will continue. Former communist countries with free healthcare, good levels of social protection, and even income distribution always had higher life expectancy compared with non-communist countries at the same level of development. Even in 2000, after the decline of the early 1990s, life expectancy in transition economies was five years higher than per capita GDP would suggest.[4] And the scores of communist and former communist countries in the Human Development Index (which includes life expectancy and the level of education in addition to per capita income) were always higher than GDP per capita scores. Will former communist countries be able to retain this advantage in the future?

Chapter 286

A THEORY OF WHY POTENTIALLY FAVOURABLE POLITICAL AND ECONOMIC CHANGES MAY LEAD TO MORTALITY CRISES

Giovanni Andrea Cornia*

University of Florence, Florence, Italy

INTRODUCTION

Potentially positive systemic economic and political changes have in the past at times entailed large transitional health costs. These have often been underestimated ex-ante and are often neglected ex-post by incumbent governments. With the aim of drawing lessons for future transformations and the actions of policymakers, this chapter reviews five past episodes of political, economic, and social transformation that were expected to improve political freedom, economic prosperity, and individual wellbeing, but that instead generated substantial increases in death rates, particularly among low-income groups. This chapter suggests that the frequency of such type of unexpected crises might increase in the future owing to the current acceleration of economic, social, demographic, and technological change.

The chapter presents a taxonomy of causal factors behind the mortality crises that followed the introduction of what were considered ex-ante positive political and economic reforms that were expected to move a country from a low a high social equilibrium. The taxonomy of factors responsible for the discrepancy between ex-ante expectations and ex-post outcomes includes: (i) the unexpected effects of rural-urban migration combined with an inelastic supply of public infrastructure; (ii) political reforms carried out in the absence of adequate administrative, legal, and redistributive institutions; (iii) the introduction of economic reforms under conditions of incomplete or distorted markets and institutions; and (iv) the unchecked contact between socio-economic groups characterised by different disease profiles.

SOURCES OF FUTURE FAVOURABLE CHANGES

The last three decades have been characterised by rapid changes in the political, demographic, technological, and economic areas. Such changes are bound to continue in the decades ahead. Far from witnessing ‘the end of history’ predicted by Frances Fukuyama, the last thirty years have seen an acceleration of change in many areas, and – as argued below – this trend is poised to continue in the years ahead. Some of the changes discussed below may be a source of gains but also of potential problems. As such, they are briefly discussed below.

To start with, since the early 1980s there has been a major paradigmatic shift towards the liberalisation of domestic and international markets and the globalisation of the world economy. This shift has taken place through a near universal application of structural adjustment programmes that limited the role of the state in the economy, privatised state assets, and liberalised labour, financial, and product markets in most developed and developing countries, and, since 1989, in the former socialist economies (Table 1). While in China and Vietnam, transition reforms were implemented in a gradualist fashion, in the former Soviet bloc they were carried out in an accelerated fashion that simultaneously entailed a swift redefinition of national borders, the introduction of new political institutions, a radical reorientation of the economy, and the adaptation of a disoriented population to a previously unknown way of life (see chapter 3). Considerable, if less dramatic, liberalisation was introduced also in the labour markets of advanced economies such as Japan, South Korea, and Italy, which as a result of these policies, experienced greater employment informalisation and instability, faster job turnover, longer search times, and a shorter duration of each employment spell. Second, the last decade also witnessed a rapid globalisation of the world economy and, in particular, an explosion of cross-border financial transactions (Table 1).

Overall, these changes seem to have generated not only some efficiency gains but also growing instability, as shown by the rise in the number of currency, stock market, and banking crises that have had devastating effects on the countries concerned and on the world economy. After the 2007-08 Lehman Brothers crisis and the 2011 European Sovereign Debt crisis, the drive towards capital account liberalisation has slowed down (Table 1, bottom panel).

Furthermore, the last three decades recorded fast progress and extensive investments in the fields of information and communication technology (ICT), biotechnology, and pharmacology. In 1990, the price of a memory chip was 1200 times lower than it was in 1975 (Pohjola, 2001) and it is continuing to fall. Meanwhile (even leaving aside the controversial GMOs), progress in biotechnology raised farm yields in several developed and developing countries. At the same time, since about 2005, productivity growth has declined in all OECD countries. This is a bit of a mystery in view of the large investments in ICT mentioned above. This might have been because R&D has diminishing returns or that it just takes time for productivity growth to pick up again as it did after the ICT revolution of the 1990s. Meanwhile, the deciphering of DNA enabled the development of a new range of ‘target drugs’ that enhance perceptibly the treatment of previously incurable diseases. Finally, the introduction of digitalisation generated productivity gains but also generated, in many countries and sectors (such as banking, insurance, and general administration), a huge substitution of labour with capital.

Note: The index of domestic financial liberalisation ranges between 0 and 10 (complete liberalisation). The Kaopen index ranges between −2.5 (closed capital account) and 2.5 (completely open capital account).

Similar or more marked effects may be generated in the years ahead by robotisation and Artificial Intelligence (AI). Robots have not yet had a big impact but the channels through which they will enhance productivity are well known (Aghion, Jones, and Jones, 2017). Nanotechnology and robotisation could one-day lead to the complete automation of manufacturing, while AI may do the same for many services. Indeed, AI seems to be poised to automate many tasks once thought to be out of its reach. It is not clear how this will affect growth, employment, the distribution of income, and wellbeing, as many tasks will succumb to automation. Only non-routine tasks requiring high levels of skill and lab-based research performed by highly skilled workers may survive. In the extreme case, AI will generate innovations itself without even the help of skilled workers. While most of these changes have had, and may have in the future, favourable long-term effects on growth, the duration of work, wellbeing, and longevity, their short-term effects are far from clear and require at least the setting up of offsetting measures in the field of employment, income distribution, leisure, and stress management. For instance, progress in the field of information and telecommunications eliminated millions of jobs and exported many more from developed to developing countries. It is likely that future changes in these areas will entail a large inter-country and intersectoral reallocation of labour that – if not properly managed – may raise personal stress and political turmoil.

Third, political systems have witnessed rapid change too. Following the downfall of Soviet-type communism in Europe and Asia, the number of countries embracing different types of political democracy literally skyrocketed. Gone, therefore, in many cases are systems

based on authoritarian regimes, military dictatorships, and neo-colonial institutions. These favourable political transitions were at times, however, accompanied by a surge in other forms of social instability, as vividly illustrated by a rise in crime rates in Russia and South Africa and – more worryingly – in the number of local conflicts and humanitarian crises.

Finally, demography has also been and will be a source of important change. While population growth declined in Europe, much of Latin America, and China, it continued increasing at a rapid rate or did not decline in Africa, the Middle East, and parts of South Asia (Table 2).

Such demographic imbalances, the persistence of intrastate conflicts often linked to ‘democratic revolutions,’ as well as the reduced cost of information about migration options, have fuelled sustained South-North and South-South legal migration, as well as a surge in the number of asylum seekers and irregular migrants. This has generated important political changes in the countries of destination. As noted by a study by UN-DESA (2017), the number of international migrants worldwide has continued increasing since 2000, reaching 258 million in 2017, up from 220 million in 2010, and 173 million in 2000.

This implies that while between 2000 and 2005, the international migrant stock grew by an average of 2% per year, the rate rose to 2.9% over 2005-2010 and it is likely it will continue growing in the decades ahead. In view of the high population growth projected for future decades in the low income South Asian, Central American, and, especially, Sub-Saharan African countries (Table 2), and of the limited job creation prospects in several source countries, it is likely that the pressure to emigrate to high-income countries will increase. In 2017, for instance, high-income countries hosted 64% of all international migrants worldwide – equal to 165 million international migrants – while 92 million migrants lived in middle-income or low-income countries. In comparison to 2000, the share of international migrants living in high-income countries increased slightly.

Indeed, high-income countries have absorbed most of the recent growth in the global population of international migrants, absorbing 64 of the 85 million migrants added worldwide between 2000 and 2017. As a result, in high-income countries the rate of growth of the migrant population rose during 2000-2017 to the 2.9% a year mentioned above, while it

fell to 1.4% in middle-income countries. Because of rapid domestic population growth, despite this continued outflow, international migrants accounted for two% or less of the total population of Africa, Asia, Latin America, and the Caribbean. By contrast, in Europe, Northern America, and Oceania, international migrants accounted for at least 10% of the total population. The number of international migrants worldwide has grown faster than the world's population. Thus, the share of migrants in the total population increased from 2.8 in 2000 to 3.4% in 2017.

Meanwhile, because of unabated internal conflicts, the global level of forced displacement across international borders continues to rise. By the end of 2016, the total number of refugees and asylum seekers in the world was estimated at 25.9 million representing 10.1% of all international migrants. The developing regions (starting with Turkey, Palestine, and Lebanon) hosted over 80% of refugees and asylum seekers in 2016. Given that a large majority of refugees are hosted by developing countries, and that many refugees reside in countries of first asylum for over a decade, there is an urgent need for the sharing of burdens and responsibility for hosting and caring for refugees more equitably.

Growing international migration has been accompanied by massive regional and rural-urban migration in developing and transitional countries, as symbolised by the acceleration in the rate of growth of cities in most of the developing world, or by the emergence of a tolerated 'urban floating population' of 120 million informal workers providing cheap labour to the construction and service sector of urban China. In both populous South Asia and Sub-Saharan Africa, the present low level of urbanisation (less than 30%) is likely to increase in the years ahead – possibly facing some of the problems encountered in the past in now developed countries. Growing rural-urban migration is often associated with a growth acceleration induced by economies of scale and agglomeration that accompany the industrialisation and overall modernisation of a country. But it is necessary to also consider carefully the problems brought about by such rapid transfers of population from the countryside, as discussed in this chapter's case studies.

On current trends, rapid change in all the variables discussed above is likely to intensify in the future. Global financial markets seem poised to continue expanding despite their high volatility and recurrent crises. And the ageing and demographic decline in the Old Continent and rapid population growth in Sub-Saharan Africa and parts of South Asia (combined with the persistence of huge differentials in living standards and human freedom between these regions) may lead to an intensification of global legal and irregular migration, regardless of the migration policies that will be adopted in countries of origin and destination. In turn, rural-urban migration will increase in both Asia and Sub-Saharan Africa. Rapid economic, social, and institutional change – in other words – is not over and, indeed, it may intensify in the years ahead.

In principle, most of the prospective changes alluded to above were supposed to have – and should have in the future – the potential to improve political freedom, living standards, and health conditions. Yet, as discussed in the case studies presented in this chapter, these potentially positive changes may take place in an abrupt, unexpected, and uncontrolled way, and in the absence of policies to improve their success and control their negative side effects. For these reasons, they may weaken collective and individual abilities to adjust harmoniously to new situations and enjoy the benefits of the changes underway. As has already happened in the past, the difficulties in foreseeing, understanding, and harnessing 'unexpected change in situations of institutional weakness' may thus entail considerable health costs, including in

terms of higher mortality. In addition, even when the aggregate health impact of rapid change may turn out to be favourable, a rise in social stratification may reduce the relative health gains of marginal groups with low levels of education, a limited capacity to participate in new economic and political institutions, or those living in remote areas. The combination of rapid change and social segmentation may thus led to a highly skewed distribution of the health gains generated by the new changes. In fact, in the past, the transition from a low social equilibrium to an ex-ante higher equilibrium seldom occurred in a linear way. In many cases, it generated large ‘transformational costs.’

Hereafter I illustrate five episodes of past and recent political and economic reforms that – despite expectations of improvements in living conditions and life expectancy – led to a surge in mortality. The chapter deliberately ignores the negative impact of recessions, contractionary adjustment policies, wars, sanctions, and environmental disasters that were indeed expected ex-ante to negatively affect the health status of the population involved. The main aim of this review is to understand the pathways that caused a health deterioration in spite of the favourable impact expected ex-ante. Tentatively, one can identify four types of situations.

PROGRESSIVE POLITICAL REFORMS AND RISING MORTALITY

The Abolition of Slavery in the US, 1850-1880

A classic example of the negative impact of a positive political change is offered by the abolition of slavery by means of the Emancipation Proclamation of Abraham Lincoln on 1 January 1863, right in the midst of the 1861-65 Civil War (Meeker, 1976). Life expectancy at birth for the black population declined sharply between the last decade of slavery (1850-60) and 1880, due to rising incidence of nutritional and infectious diseases such as smallpox and cholera. Downs (2012) estimates that about a quarter of the 3.1–4 million liberated Southern slaves either died or suffered from serious illness between 1862 and 1870. The primary reason for the rise in death rates was not so much a change in disease patterns and medical practices, but the disruptions in social organisation and living conditions associated with the abolition of slavery. During the era of slavery, the health and nutrition of slaves depended on their owners, who had an economic incentive to keep them in good health. The health and nutrition of the freed black population, in contrast, were influenced by their inability to obtain medical care from a non-existent public health system and costly private providers while the Northern political authorities did not introduce any basic health schemes for them. Declines in health status were also due to negative changes in housing conditions and income-earning opportunities. Many freed slaves were placed in unhealthy ‘contraband encampments’ near union army barracks, and were unable to obtain compensation for their enslavement or land to grow food, a fact that reduced their agricultural output and food intake. Most of them had in fact to survive by selling their labour as casual workers during a period of extreme turmoil.

Thus, while the abolition of slavery was a noble and idealistic decision, as well as a shrewd political manoeuvre by Abraham Lincoln who, in this way, increased the number of soldiers fighting for the North by 200,000 units, the freeing of the 3.1-to-4 million slaves in

the South without simultaneously ensuring them minimum income-earning opportunities and access to basic housing and health turned out to be the cause of sharp health deteriorations.

The South African Transition to Democracy, 1989-2004

South Africa's transition from a supremacist regime to a multiparty 'rainbow' democracy was not an easy one (Desmond and Boyce, 2003). The country experienced two different, if interconnected, transitions. The first was from Apartheid to democracy, the second from an inward-looking to a neoliberal market economy.

The political transition had began in the late 1970s and early 1980s with the introduction of a few adjustments motivated by the poor economic performance of the country and the desire to raise an abysmally low supply of skilled African workers, whose shortage was a key factor in limiting growth potential and domestic demand. The years between 1982 and 1987 saw the creation of the first political organisations, the dismantling of petty Apartheid, and the creation of the Tricameral Parliament. Despite these concessions, political violence intensified. The state responded in 1986 by declaring a state of emergency, handing over power to the security establishment, and launching urban renewal programmes in townships characterised by political tensions. This response raised death rates among the black population and, to a lesser extent, among the white population. By the early 1990s, political compromise began to prevail, leading to the end of Apartheid in 1994.

The newly acquired political freedom was accompanied by considerable debate about the choice of policies in the field of nationalisation, land reform, fiscal policy, taxation, and FDI. In the end, the ANC government gave priority to growth driven by the 'trickle down approach' and the provision of urban basic services to reduce poverty and tensions. The neoliberal nature of these reforms became clearer with the adoption in 1996 of the Growth Employment and Redistribution (GEAR) programme that focused on private investment-led growth, with no explicit targets for the reduction of poverty and inequality.

The restoration of democracy, end of sanctions, and election of a government committed to social change were expected ex-ante to positively affect growth, poverty reduction, and health status. However, existing data do not enable the tracing of the health impact of the transition due to long-standing registration problems and the blurring effect of HIV-AIDS. Nevertheless, the available evidence suggests that – on balance – the positive political reforms introduced since 1994 did not improve health status. Three factors explain this unexpected outcome.

Table 3. Income distribution changes in South Africa, 1991-2001

Households	Share of total income			Changes	
	1991	1996	2001	1991-1996	1996-2001
Bottom two quintiles	3.8	3.4	3.3	-11.0	-3.0
Third quintile	7.6	7.4	7.3	-0.3	-0.1
Fourth quintile	17.6	17.4	17.2	-0.1	-0.2
Top quintile	71.0	71.8	72.2	1.1	0.6

Source: Adapted from Terreblanche (2002), p33, cited in Desmond and Boyce (2003).

Economic performance improved only modestly in relation to the Apartheid years. Per capita income growth was negative over 1990-5 and barely turned positive after 1996. Meanwhile, income inequality worsened (Table 3). As a result, poverty increased, with likely negative effects on health. This disappointing performance can, at least in part, be attributed to the legacy of Apartheid. Yet, the key issue was that while GEAR improved the macro fundamentals, it failed to create jobs (Streak, 2004; and Terreblanche, 2002; cited in Desmond and Boyce, 2003). As a result, poverty and inequality continued to increase in the second part of the 1990s.

Public policy deliberately aimed to improve social conditions. Government spending on health, welfare, education, and housing rose from around 50% of non-interest expenditure in 1990-91 to an average of 60% between 1995 and 2002. Free healthcare was made available to pregnant women and small children, a school-feeding scheme was started, healthcare was decentralised and a programme of clinic building and renovation was initiated. Though hampered by limited capacity and expenditure constraints, these programmes were expected to favourably affect health and start reversing long-standing health inequities. Nevertheless, in the end, only 20% of the poor received a grant, owing to limited fiscal capacity (Streak, 2004). Another priority of the new government was to increase access to water, sanitation, and electricity, and as a result, the availability of piped water rose from 78 to 83% between 1995 and 1999 (Desmond and Boyce, 2003). Despite these improvements, the country experienced two cholera epidemics after 1994, because the programme did not reach the ultra-poor and due consumption remaining low because of high costs and distance.

With the removal of influx control, rural-to-urban migration to already overcrowded townships rose sharply due to lack of employment opportunities in rural areas. The new government embarked on a massive low-cost housing programme that produced over a million new homes after 1994, with the result of raising the share of families living in formal housing. Yet, for a variety of reasons, including an acceleration of rural-urban migration, the share of households living in informal housing rose from seven to 12% during the same period, thus offsetting the impact of the programme in reducing the spread of TB, pneumonia, and HIV.

A second unexpected pathway through which the political transition affected health status was via a surge in violent deaths and political assassinations that increased sharply over the 1987-1990 period, then to subside from the early 1990s. As a result, cases of political violence in urban areas fell from 2,500 in 1990 to less than 500 in 1994 (Barbarin et al., 1999). Yet such a fall appears to have been accompanied by a rise in criminal violence (*ibid*). Indeed, the political transition occurred in an environment of widespread violence, easy access to weapons, little confidence in an ill-equipped police force and weak capacity of the criminal justice system. During the Apartheid years, civil disobedience, boycotts, and even political violence were widely considered legitimate tools of political struggle. In turn, the state responded to these acts in an even more brutal way. All this contributed to the creation of a culture in which violence was the main tool for resolving all political and personal disputes.

The longer-term impact of all this was a sharp rise in criminal activity and violent deaths between 1987 and 1990 and after 1990. Between 1980 and 1990, the murder rate rose by 32%, rape by 24%, and burglary by 31% (Shaw, 1996). In turn, over 1990-94, the number of murders fell only marginally, from 16,000 cases in 1990 to close to 15,000 in 1994, as the fall in political assassinations was almost completely offset by a rise in criminal ones. In addition,

other crimes continued to increase, with assaults climbing by 18%, rape by 42%, robbery by 40%, and burglary by 20% (ibid). By 1996, hospital records showed a daily average of 2,500 South Africans received treatment for stabbings, assaults, and shootings. Data for 1994–1997 from the key districts of Soweto and Gauteng confirm the trend towards falling political brutality but rising criminal violence (Barbarin et al., 1998). The sense of insecurity and fear of being attacked while at home or in the street rose for all ethnic groups. Such fear and stress-related mortality may be another channel through which the transition affected health status.

Finally, over the 1980–2005 period, South Africa experienced an HIV-AIDS epidemic, the incidence of which started declining slowly only from around 2005. No doubt, the epidemic would have occurred regardless of the political transition, but the latter may have accelerated its diffusion. The removal of control on internal migration, political violence, and reforms-induced urbanisation increased mobility within the country, thus facilitating the spread of the epidemic. The increase in rape associated with political violence was another means of infections. The inefficient management of the healthcare system during the reform process reduced the quality of medical assistance (Desmond and Boyce, 2003). Finally, by attracting most of the public attention, the political transition inadvertently contributed to a neglect of the disease and of the initial signs of its diffusion.

While the overall effect of the transition was certainly positive, path dependence and the adoption of neoliberal policies did not enable achievement of better health outcomes. In turn, fiscal restraint prevented benefits from new expenditure priorities being realised. Therefore, while if compared to no action, health outcomes have most likely been better because of the transition, they are possibly not what they could have been if some of the problems discussed above had been anticipated.

RURAL-URBAN MIGRATION, INADEQUATE PUBLIC URBAN INFRASTRUCTURE, AND RISING MORTALITY

A third case in which potentially positive long-term changes can lead to a worsening of health conditions concerns the unplanned acceleration of migration to urban areas. Over the short-to-medium term, uncontrolled migration has been shown to reduce life expectancy in several cases. Indeed, while higher incomes per capita, improved access to public services, and enhanced collective hygiene generally lessens mortality over the long term, the short-term effects can be quite negative. A first cause of this problem is the rigid supply of social infrastructure. While city-based industrialisation offers more jobs and higher wages than in the countryside, the inability to rapidly expand water, sewerage, and transport services can raise the incidence of airborne, waterborne, and infectious diseases in peripheries that have become reservoirs of various kinds of epidemic. A second cause concerns the equally rigid supply of housing. The result is overcrowding in low-standard barracks where bad hygienic conditions create an inviting milieu for tuberculosis and other infectious diseases. A third factor relates to human behaviour. Immigrants mostly come from rural societies where strong social control prevails and opportunities for deviant behaviour are few. Once in the cities, the new immigrants can easily be lured into deviant activities or the consumption of alcohol, drugs, or other substances that increase the risk of violent death.

Rapid Urbanisation and Mortality Increases in 19th-Century Britain

An example of deterioration in mortality during a period of growth and overall improvement in living standards is that observed during the rapid industrial growth of the second and third quarter of the 19th century in Britain (Szreter, 1997). During this period, mortality deteriorated because of the disruptions caused by rapid urbanisation, the inadequate development of water and sanitation systems, residential segregation, and rising income and wealth inequality. While during the period of moderate growth of 1730-1820, nationwide life expectancy at birth rose from 32 to 40 years, between the 1820s and 1870s large industrial cities such as Manchester and Liverpool and small but fast-growing towns experienced an upsurge in mortality. The rise in mortality was mainly due to the spread of infectious and waterborne diseases, particularly among the infants of new migrants who lived in quarters without safe water supply and adequate sanitation. As a result, life expectancy in these cities did not rise, and fell by about one year in some of them, despite a steady increase in urban wealth.

More generally, distress migrants – and especially their children – face greater mortality risks than people who remain in their community. Poor migrants often do not have the resources to access the rental market and – in the absence of public interventions in the housing sector – end up living in slums characterised by the lack of basic water, sanitation, and power supplies. Indeed, because of the considerable costs and time required to develop basic urban infrastructure, a rapid surge in migration tends to be accompanied by overcrowding and poor sanitation and reduced access to potable water. In addition, distress migration entails considerable material hardship, disorientation, the inability to operate easily in new environments, the breakdown of social relationships, redefinition of survival strategies, and greater stress. Unsurprisingly, in very many developing countries, while the Infant Mortality Rate (IMR) of urban areas is consistently lower than that of rural areas, IMRs in slums – especially slums hosting new migrants – are higher than the average for rural areas.

The policy message of the Szreter study is clear. While ‘governed migration’ has been shown to generate considerable productivity and welfare gains in both places of origin and destination (Williamson, 1996), sudden and uncontrolled surges in migration tend to generate pressure on urban infrastructure and rental prices, overcrowding, and the risk of spreading infectious, waterborne, and other ailments among both the migrant and local populations.

Rising Male Mortality during the Urbanisation of Sweden, 1810-50

Until the early 19th century, Sweden was an agrarian society dominated by Lutheran values where the church exerted strong social control on the rural population (Sundin and Willer, 2002). The transition from this pre-industrial society began with the slow urbanisation of the early 1800s, though significant industrialisation took off only after 1849 and peaked around 1870. Indeed, new farming techniques increased productivity in agriculture and so released part of the rural workforce that migrated to the cities to find jobs as servants or unskilled labourers in small foundries and sawmills.

This migration was accompanied by perceptible demographic and social changes. To start with, the difficulties encountered in finding steady jobs in the cities raised the average age of marriage among the lower classes as well as the illegitimacy rate, a trend made possible by the loosening up of social control. The crime rate rose too, in parallel with growing social polarisation and alcohol consumption. Violations ranged from minor episodes, to aggression against members of the upper class, to theft and homicide. Health status showed important changes during this period. While mortality among children and women declined, that among adult males rose or stagnated at high levels. IMR declined steadily from 190 per thousand in 1810 to 120 per thousand in 1860 (ibid), thanks to the growth in food production, spread of health infrastructure, and improved urban sanitation (Edvinsson and Nielsson, n.d.). For instance, a growing number of district physicians and trained midwives offered greater curative care and actively promoted breast-feeding, modern childcare practices, and child immunisation. In the cities, the decline in infant mortality was also driven by improvements in sewerage, garbage collection, and protection of water sources (this point is however questioned by Edvinsson and Nilsson, n.d.). Mortality among young and middle-aged women followed a pattern similar to that of children, likely because of the general improvement of nutrition and sanitary conditions and the rise in the proportion of births assisted by trained midwives. Yet, for older women, mortality did not decline at the same pace, because of the material deprivation in which poor spinsters and widows had to live.

In contrast, mortality among men rose and remained at levels higher than that of 1800 until around 1840–50. This meant that the male-to-female mortality differential – already high prior to 1810 – rose further during the first half of the 19th century. The biggest male-female differentials were recorded for deaths due to alcohol intoxication, accidents, violence, suicides, and tuberculosis. This rise in the mortality gap was not so much due to differences in income, as men's salaries were generally higher than those of women, but rather to differences in lifestyle. Unmarried men were more likely to adopt unhealthy behaviour, while unmarried women internalised gender roles emphasising quieter conduct and participation in supportive social networks. For men, secularisation, greater anomia, and the decline of social control that accompanied migration to the cities led to the adoption of more violent and risky lifestyles. In addition, the old norms of reciprocity and survival strategies of the agrarian society no longer worked in the cities. Finding oneself in a new milieu often generated a sense of being uprooted, especially for those lacking kinship networks on which to rely in case of need. Under these new circumstances, alcohol emerged as an important stress reliever.

Although there are no reliable data for the first half of the 19th century, several factors suggest there was a substantial increase in alcohol consumption during this period. For instance, registered deaths due to alcohol intoxication peaked in the 1840s (Sundin and Willer, 2002). In towns, alcohol could be bought everywhere at a low price and restrictions on production and sales were minimal. Certainly, the mortality impact of alcohol consumption was greater than that indicated by the registered cases of acute intoxication. Heavy drinking affected also nutritional status, housing conditions, and hygiene. Even lung diseases, strokes, accidents, and suicides occurred in part due to excessive drinking. Another factor that contributed to the adverse mortality trend among adult males was the slow improvement of public sanitation. As in the United Kingdom, the development of public water and sewerage systems in the new settlements inhabited by migrants in fact lagged behind the growth of cities and so contributed to a rise in deaths due to waterborne and airborne diseases.

CONTACT AND CONTAGION BETWEEN HETEROGENEOUS POPULATIONS

The demographic crisis that hit Panama City and Colon on occasion of the construction of the Panama Canal is a good example of the economic, social, and environmental imbalance in various parts of Panama, including in its rainforest, generated by the massive influx of workers. The arrival of the French Canal Company was expected to generate a favourable impact on employment, growth, and health. However, it instead led to speculative increases in rents and food prices that made the life of poor Panamanians more difficult (Jackson et al., n.d.). In addition, the intrusion into Panama's rainforest upset the delicate balance between urban and forest disease pools.

An analysis of the death registers of two parishes shows a marked if diversified increase in mortality over 1884–89, which is the period of the first attempt to build the canal by the French Canal Company. During this period, diseases such as malaria and yellow fever – the etiologies of which were not fully grasped at that time – decimated the workers of the French Canal Company and took the lives of approximately 20,000 able-bodied workers (Mina Stern, 2005). The analysis of death registers also shows a major mortality decline between the period 1884–89 and the 1890s, which are the years in which the project was abandoned and mortality returned to its normal level. Finally, it also shows a sharp mortality differential between the poor parish of Santa Ana and the better off La Merced. Indeed, between 1884–89 and 1889–93, death rates dropped from 38 to 13 per thousand in La Merced and from 66 to 28 in the poor neighbourhood of Santa Ana.

How did the construction of the Canal cause such a health crisis? The influx of thousands of West Indian workers caused overcrowding and severe sanitation problems in the urban areas of the city. Overcrowding facilitated the spread of contagious diseases, while the deterioration of drainage and garbage collection created numerous locations for mosquitoes to breed. Since these were the main vector for malaria and yellow fever, the incidence of both maladies rose sharply in urban areas. However, mortality rose as sharply in the work camps along the Canal route, if for a different reason. Indeed, thousands of workers came into contact with a mosquito unique to the Panama rainforest and endemic in wild primates living in it. This mosquito acted as the main vector of yellow fever, thus sharply increasing the contagion in the work camps.

With the suspension of the construction of the Canal and the exodus of the workers, the mortality crisis abated. The construction of the Canal was resumed by the US government, which took possession of the Isthmus of Panama in 1903. The large-scale effort was not followed by a mortality crisis like that of the 1880s. The US government had learned the public health lesson of the first attempt and instituted large-scale public health measures to eliminate the threat of yellow fever, malaria, and other tropical diseases before continuing the construction of the Canal to its completion. President Roosevelt dispatched a public health team to Panama with the brief of eliminating the mosquitoes carrying yellow fever and malaria. This was achieved through the systematic destruction of the mosquito larvae, eliminating any body of standing water (such as water tanks and cisterns), by introducing quarantine stations, increasing the supply of running water, and introducing other public health measures such as fumigation and garbage collection, which led, among other things, to the eradication of yellow fever from the area.

LIBERAL MARKET REFORMS AND HEALTH CRISES

In some cases, the introduction of potentially beneficial economic reforms generated negative health outcomes (see also chapter 3 of this volume). A first explanation of this unexpected outcome is that reforms were applied under conditions of incomplete markets and institutions. Another explanation focuses instead on the problems caused by incomplete reforms, as the changes introduced were only a subset of those that needed to be introduced. This means that each reform taken alone may not generate improvements that depend on simultaneous changes in many areas. A third explanation concentrates on the ‘sequencing problem’ that arises when reforms are introduced in the wrong order. This problem is well known in macroeconomics (when, for instance, the liberalisation of capital movements takes place before macroeconomic stabilisation is achieved) or in transition economics (when price liberalisation and privatisation were introduced before competition reforms were introduced). A final explanation focuses on workers and entrepreneurs and their ‘inability to adjust’ to sudden and unanticipated changes in economic circumstances.

Hereafter we discuss the case of market liberalisation and the rising suicide rate among cotton farmers in Andhra Pradesh over 1997-06. In spite of its recent success in diversifying its economy, in the late 1990s and early-mid 2000s, India still depended on agriculture as the main source of livelihood for 70% of its population. It is no surprise, therefore, that in the 1970s and 1980s, the years of the Green Revolution, policymaking focused strongly on this sector. Indeed, success in raising agricultural output and reducing rural poverty during the 1980s depended to a considerable extent on policies that increased public support in the field of rural credit, input subsidies, and stable input and output prices.

However, following a severe macroeconomic crisis, in July 1991 the government introduced a new policy approach emphasising the reduction of state controls, subsidies and investment in agriculture, the enlargement of the role of the market, and greater integration with the global economy. Within this approach, the agricultural reforms emphasised a reduction in price support and input subsidies, the encouragement of subsistence farmers to enter input-intensive productions for the domestic and international markets, and the liberalisation of the imports and exports of agricultural commodities. In particular, subsidies on fertilisers, electricity, irrigation, and credit were reduced, interest rates on farm loans liberalised, and rural banking privatised. In political-economy terms, such changes signalled the marginalisation of the farming community in the policymaking process.

When markets are complete and function well, the kind of reforms introduced in India in 1991 may lead to a more profitable allocation of resources among crops, continuous adjustments to changing market opportunities, faster growth of agricultural incomes, and better health for rural dwellers. Such a policy approach was, however, far less favourable in many areas of India during the 1990s and 2000s, in part because of the weakness of the safety nets established to deal with the transitory costs associated with the liberalisation of agriculture, but mainly because of the inherent weaknesses of credit, insurance, input and output markets, and a surge in uninsured price volatility following the globalisation of Indian agriculture. Lack of statewide regulation also led to a ‘fallacy of composition’ as many farmers experienced increased dependence on groundwater and credit to finance a growing number of bore-wells. This led to a rapid depletion of the water table, followed by repeated attempts to deepen the wells. Galab, Prevathi, and Reddy (2012) report the case of a village,

where 35 years ago, there were only six tube-wells and the water table was at six feet from the surface. Yet, by 1998, there were 1,800 bore wells, half of which were dry, and the water table had fallen to 240 feet.

The first spurt in farmers' suicides occurred in 1986-87, i.e., before the introduction of the neoliberal reforms of 1991 mentioned above. There were also a few cases of suicide in later years, but these early warnings of rural stress were ignored as aberrations. It is with the second spurt that began in 1997 that the farmer suicide problem intensified and became a structural phenomenon.

One of the districts where the impact was most visible is the semi-arid and so-called 'backward' Warangal district of Telangana state in Andhra Pradesh, which experienced a surge in suicides among small cotton farmers over 1998-2006 and beyond (Table 4, left panel). A study by Sudhakumari (2002) covering the years 1997-2002 analysed the economic circumstances of the households of 50 randomly selected suicide victims who lived in 5 Mandals of Warangal, the district that recorded the highest number of suicides in Andhra Pradesh. The study shows that 66% of the farmers who committed suicide were less than 40 years old, an age group usually characterised by a low suicide rate, while 48 of them were male, and all were married and belonged to low-income families with limited resources and education. Indeed, 31 out of 50 were illiterate, 44 belonged to 'backward' communities or scheduled castes, 18 were landless leaseholders, and 22 had less than 2 acres of land.

Galab, Revhati, and Reddy (2012) extend analysis to 2006 using a broader information basis (including the systematic compilation of suicide reports mentioned in the local Telugu press) and focussed on four districts, one of which was Warangal. Except for the latter, agriculture was the main source of income in each district. Their study confirmed the findings of Sudhakumari (2002) about the socio-economic characteristics of the farmers that committed suicide. In particular, they found that 86 to 97% of the deceased were men in the 30-50 age group. 46-63% were illiterate and belonged to 'Backward' Castes and Scheduled Castes and Tribes. The majority were marginal and small farmers (who experienced higher suicide rates than farmers with a few hectares of land) while some 10-15% were tenants or tenants cum-owner and upwardly mobile middle level farmers.

The study by Galab, Revhati and Reddy (2012) and the studies cited therein identified the main correlates of the increase in suicides. These included dependence on ground water (i.e., dug wells and bore wells) as a source of irrigation; a high share of non-food commercial crops in total output; dependence on expensive informal credit for working and fixed capital (89% among micro farmers versus 50% for farmers with more than 10 hectares); high dependence on market inputs; the volatility of output prices, and the proportion of income that farmers were forced to spend on education, health, and social events. In contrast, the risk of suicide fell when the sources of household income were more diversified.

These personal correlates point to a class of ill-trained and ill-financed small farmers who entered commercial production without the technical support needed to deal with the complexity of the new productions, or adequate arrangements to withstand the problems caused by incomplete credit and insurance markets and volatile world commodity prices.

What led to the increase in suicides? During the period under examination, Andhra Pradesh was affected by adverse weather and pest conditions that caused severe crop losses and could have – in principle – contributed to a surge in suicides. However, such problems were not new in the region and had not caused any perceptible rise in suicides in the past. The cause of the crisis therefore lay elsewhere.

Table 4. Suicides among cotton farmers in Warangal district and Andhra Pradesh, 1997-2006

Year	Number of suicides in Warangal		Number of suicides in Andhra Pradesh	
	Sudhakumari (2002)	Galab, Revathi and Reddy (2012)	Sudhakumari (2002)	Galab, Revathi and Reddy (2012)
1997	16	52	28	108
1998	109	69	307	190
1999	71	100	211	180
2000	50	98	147	220
2001	31	119	89	357
2002	39	123	120	328
2003	---	92	---	342
2004	---	88	---	1795
2005	---	51	---	617
2006	---	26	---	369
Total	316	819	902	4403

In Warangal and the other three villages analysed, the drive to integrate subsistence farmers into the market economy also entailed a considerable increase in the input-intensity of production, particularly in the case of cotton, a crop that requires improved seeds, electricity, water, fuel, fertilizers, and pesticides. Expectations of high world prices, encouragement to enter commercial farming by the local government and private distributors of seeds produced by multinationals convinced many small farmers to shift from low-risk/low-input subsistence crops to high-risk/high-cost export crops with potentially high-returns. As a result, the area under pulses fell, that under wheat and rice stagnated, and that under commercial crops rose. For instance, in Warangal, 89% of the families of the farmers who killed themselves grew only cotton.

Second, the change in the crop mix and the subsidy cuts mentioned above caused considerable shifts in the economic circumstances of small farmers. To start with, the input intensity of production rose in line with the shift to export crops that required much larger input costs per acre. For instance, in the late 1990s, land cultivated with cotton entailed an expenditure of 18,250 rupees per hectare, against one of 4,700 rupees for maize. As four-fifths of the cultivable land in the region needed irrigation, the shift to cotton induced a sharp increase in capital and recurrent costs for well irrigation. Dependence on purchased seeds increased as well, right after seed subsidies were withdrawn, a fact that caused a large rise in seed costs for farmers.

Table 5. Structure of the indebtedness of the farmers (Rupees)

Sources	Total amount borrowed	% of total borrowing
Commercial Bank	343,012	8
Co-operative Bank	214,382	5
Money Lender	1586,430	37
Pesticide Shop Owner	728,900	17
Middle Man	1200,342	28
Private Financial	85,753	2
Institutes/Friends/Relatives	128,629	3

Source: Sudhakumari (2000).

Third, the purchase of growing amounts of inputs entailed a rise in the borrowing requirements of small farmers. While under normal market conditions, the latter would have counted on a capillary banking system providing credit at competitive rates, the weakness of the local financial sector, the exclusion of a third of the deceased farmers from credit because they did not own the land they cultivated, the retrenchment of institutional credit, and the crisis of cooperative credit pushed the small farmers into the arms of moneylenders and pesticide dealers (Table 5) who charged interest rates ranging between 36 and 60%.

A fourth factor was the volatility of cotton prices. Trade liberalisation exposed the Indian farmers to the vagaries of global commodity markets, without providing them with any mechanism (such as crop insurance or a price stabilisation fund) to compensate them for swings in world prices and international competitiveness. While in 1994–95, the domestic price of cotton rose steeply, it then began to fall, against all expectations, from 1997, in line with the decline of world prices and the rise of cheap imports. In addition, credit dependence on moneylenders and middlemen forced the indebted farmers to sell them most of their output at prices below those prevailing on the local market. Government policies did not help either as they allowed the textile mills to import cheap cotton lint despite the existence of a growing domestic cotton surplus. Thus, from the perspective of becoming an exporter, the country became an importer of cotton produced in countries that subsidised its production and sale.

The withdrawal of input subsidies was a fifth source of economic stress. As noted, after the introduction of structural adjustment policies in 1991, the price of fertilizers doubled while subsidies to canal irrigation and electricity were cut. Public investment in irrigation fell to a minimum, thus unloading the cost of irrigation onto the farmer. A final factor was the failure of public extension services that, during liberalisation, suffered a major reduction in the number of agricultural officers. Even though the agriculture department was well aware that the red soils of Warangal were not suitable for cotton cultivation, they never advised the farmers to stop growing cotton or bothered to advise them about the proper amount and type of pesticides required per acre. As a result, 83% of the households interviewed in Warangal cultivated cotton based on limited knowledge or depended for new information on unscrupulous private dealers of pesticides and seeds who often provided interested and inaccurate advice and sold low quality seeds and inputs.

The rise in the suicide rate in Andhra Pradesh shows that three interlinked factors – the instability of globalised agriculture lacking any insurance or price stabilisation mechanism; the decline in state support to public investment, rural credit, and agricultural extension; and the absence, inefficiency, and interlocked-ness of liberalised output and inputs markets – played a key role in raising indebtedness and economic desperation among cotton farmers. Some cotton farmers – facing a major dislocation of their livelihoods – experienced despair, loss of self-respect, and the inability to cope with such cataclysmic changes so that, in the end, they took their lives. Galab, Revathi, and Reddy (2012) place the Andhra Pradesh suicide crisis in the context of the agrarian crisis that affected the state and argued that the suicide increase was only a symptom of a broader crisis that emanated from population pressure and falling farm sizes; the introduction in the early 1990s of rural reforms that were insensitive to the regional specificity of agriculture; the erosion of public institutions for agricultural extension, credit, coordination, and public investment; the adoption of yield-increasing technologies without the prior introduction of adequate infrastructure and state coordination and without resolving the problems caused by an irrational distribution of land prior to the introduction of the reforms.

CONCLUSION

This chapter has argued that profound social changes such as those observed on occasion of important political or economic reforms may have unexpected and long-lasting negative effects on the health conditions of large sections of the population. The analysis of past and current cases of social change confirms that the search for political and economic improvements may lead to considerable social dislocations and severe mortality crises over the short and medium term.

The chapter (as well as chapter 4) has also argues that the mortality crises that have followed episodes of rapid social change or epochal transitions have affected different social classes, although in the majority of cases low-income groups were most affected. Among the latter, one can include immigrants to cities (as in the case of urbanising Britain and Sweden), workers in cities exposed to problems of overcrowding, inadequate housing, and sanitation, workers exposed to an untouched pool of diseases (as on the occasion of the construction of the Panama Canal), illiterate, low-caste cotton farmers (as in Andhra Pradesh), freed slaves (as in the US), and an underclass of newly unemployed workers with low education, living in incomplete families, and from a minority background (as in several Eastern European economies in transition; see chapter 3). In some cases (as in Panama and South Africa), the crisis also affected part of the middle and upper class, indicating that while these crises may hit the lower strata of society particularly hard, better-off groups cannot consider themselves immune from problems. Evidence also suggests that the stronger the initial stratification, the higher the likelihood that low-income groups will be disproportionately affected, leading in this way to a widening of health inequality and possible political turmoil.

The chapter has also suggested that these mortality crises have generally affected two well-defined age-gender groups, i.e., adult males and children. The analyses of Andhra Pradesh, Sweden, South Africa, and the European economies in transition (see chapter 4) show that adult males are especially vulnerable to stress-related mortality, their greater vulnerability being due to differences in behaviours and gender roles rather than biology. Mortality crises have also hit some biologically vulnerable groups, such as infants and children, especially when the main causes of death were infectious, nutritionally related, respiratory, and waterborne diseases.

There appears to be four broad pathways through which potentially positive social change may adversely affect health status: (a) due to the unexpected effects of political transitions carried out in the absence of adequate administrative, legal, and redistributive institutions and a modicum of economic democracy; (b) through increased geographical mobility combined with the inelastic supply of health infrastructure and housing leading to overcrowding, deteriorations in environmental conditions, and the rise of infectious and social diseases; (c) via the introduction of economic reforms under conditions of incomplete markets and missing institutions; and (d) due to contact between different pools of disease.

While the pathways through which rapid change impact mortality for infectious and poverty-related diseases are well known, less is known about the economic and social factors that may raise stress levels among populations affected by rapid change. Such factors (such as rising unemployment, the inability to honour economic commitments, and the fear of violence) are generally unexpected due to never having been experienced before, or because people only have generic expectations about the probability of their occurrence. Unexpected

events cannot be insured against or prevented through structural interventions. At the time, social change is also sudden, a fact that compresses the response time available to society and communities to introduce counter-measures to offset its impact.

Because of people's inability to prepare for and deal with rapid change (even if potentially favourable), it can increase the sense of uncertainty about the future, the fear about one's own security, the perceived risk associated with human activities, the sense of loss of control and self-confidence, and psycho-social stress. The breakdown in social networks and the lack of institutional responses and practicable coping strategies tend to aggravate the situation. In addition, growing uncertainty has well-known economic effects including an increase in the riskiness of investment, a rise in interest rates, and higher savings propensities and risk aversion, i.e., changes that depress the current levels of investment and production. Rapid and unexpected change may also increase sectoral and spatial mobility and organisational change, in this way increasing anomy and eroding social capital, the sense of community participation, and the ability to undertake collective action. In times of rapid change, old rules, norms, and institutions no longer function as efficiently as they did in the past. If pre-existing informal institutions – such as voluntary associations, social networks, religious institutions, the family, and other primary support groups – are weakened, it is likely there will be nefarious effects for social stability and security.

The nature and breadth of public response to crises induced by rapid change have varied sharply. Yet less is known about why some societies respond in a collective fashion to the dislocations caused by social change while others do not (Eyer and Sterling, 1977). Initial social stratification, as well as political ideology, have affected the willingness and ability of governments to respond to health crises once these have exploded. In egalitarian societies, public policy deliberately aimed at containing the health impact of transformational recessions. In turn, in the highly polarised Southern States of the US, the health and nutrition problems faced by the disenfranchised slaves took a very long time to be addressed. Likewise, in the highly unequal economies in transition of the Russian Federation and South Africa, the crises were dealt with only in part by national authorities. One of the possible explanations of this kind of policy stance is that the new elites of an increasingly unequal society were not concerned by a crisis that mostly hit an economically and politically disorganised group of marginal people with low levels of education and skills, poorer jobs, and lower incomes, and poorer political representation. Truly democratic and participatory societies appear better able to respond to the social and health challenges posed by rapid economic and social transformations. The same can be argued for societies benefitting from a wide range of genuine 'intermediate institutions' that help to channel political consensus, keep up the pressure on incumbent governments, undertake collective action, and defend the interests of the most vulnerable sections of society.

The acceleration of technological, institutional, policy and demographic changes observed over the last two decades is likely to continue in the years ahead. In view of this, the lessons of recent or past cases of political, economic, and social upheaval constitute a valuable lesson for understanding the potential health impact of expected future changes that are already on the horizon or are likely to emerge soon, such as Africa's accelerating mass migration towards Western Europe or the employment impact of robotisation. It is therefore essential that policymakers systematically analyse the evidence on the health impact of past systemic changes before new changes occur. Only this can constitute an efficient guide to policymaking that aims to prevent important dislocations during an era of rapid change.

Chapter 287

MORTALITY CRISES IN HIGH-INCOME COUNTRIES: EVIDENCE FROM THE UNITED STATES, THE UNITED KINGDOM, ITALY, AND GREECE

Roberto De Vogli*
University of Padua, Italy

INTRODUCTION

Over the last decades, life expectancy at birth (the average number of years a newborn would be expected to live if a set of age-specific death rates in a given year continues to apply) has increased steadily all over the world (World Health Organization [WHO], 2006). Although quality of life may be even more important than the quantity of years a person is expected to live, life expectancy at birth is generally regarded as the most important measure of the overall health status of a population. This indicator is widely used by policymakers, the public, media, and other key societal stakeholders to compare and measure progress in the health of people and assess the quality of a health system in delivering optimal health outcomes.

Thus, if we assess the world's health by using life expectancy at birth, one can easily infer that people all over the world have never been healthier than today. In the last centuries and especially in the last decades, both adult and infant mortality rates have steadily decreased in all regions of the world. Yet, in spite of such improvements, the world is still facing numerous health challenges, including the high inequalities in longevity between socioeconomic groups as well as numerous cases of sudden "health reversals" or unexpected increases of cause-specific death rates and even all-cause mortality rates. Are these mortality crises happening by chance? Or are they by-products of some key determinants of health? Are there country-specific mechanisms behind such mortality crises or are there general patterns of explanations? Are these crises avoidable and what policy changes can prevent them in the future?

* Corresponding Author's Email: roberto.devogli@unipd.it.

Although there is no exact definition of health crisis, it is simply referring to a sudden increase in the level of mortality due to a wide variety of determinants of health (Bacci, 2000). Throughout human history the most important determinants of mortality crises included material conditions such as the plague or epidemics of infectious diseases, absolute poverty, famines, wars, and other natural occurrences. Material deprivation is still responsible for a high proportion of deaths today, especially in the developing world. Yet, as socioeconomic conditions have been improving over the centuries and especially in the last decades, material determinants of health such as epidemics, famines, and absolute poverty have played an increasingly relatively less important role in explaining modern mortality crises. Instead, psychosocial determinants such as mental health problems, social isolation, hopelessness, stress, and meaninglessness have become more and more relevant in understanding trends in population health in high-income countries. As often noted by epidemiologists, quoting a very popular definition of the WHO, health is far more than the absence of disease (an outcome of material circumstances), but should be viewed as “a state of complete physical, psychological and social wellbeing.”

Rather than providing a comprehensive picture of recent mortality crises, this chapter addresses a few examples and case studies from high-income countries. The chapter focuses particular attention to four countries for analytical comparison: the United States, the United Kingdom, Italy, and Greece. First, it examines potential explanations for the recent unexpected reductions in life expectancy in high-income nations including these four countries. Then, it investigates the multiple determinants of the sharp and surprising rise of mortality due to suicides, alcohol abuse, and drug overdoses among middle-aged White Americans since the early 1990s, a time of steady health improvements for all other ethnic and age categories. The rise of these so-called deaths of despair followed the adoption of a trade liberalisation treaty with China that cost about 6 million job losses in the manufacturing sector in the United States. Finally, the chapter will focus on the mental health crisis (the rise of suicides and mental health illnesses) in the United States and Europe after the outbreak of the 2008 global financial crisis that heavily affected the United States, the United Kingdom, Italy, and Greece. It will also analyse the health effects of austerity measures that were adopted by all four countries (though in different degrees) to reduce mountain budget deficits.

A key objective of the chapter is to assess common determinants and shared patterns of explanations for these mortality crises and identifying different possible mechanisms connecting political and economic changes, psychosocial factors, and unexpected increases in mortality. The final part of the chapter will include a discussion of future research and implications for policy and health promotion as well as an analysis of policy responses by different countries affected by economic crises and social instability.

‘HEALTH REVERSALS’: THE UNEXPECTED DECLINE OF LIFE EXPECTANCY AT BIRTH IN HIGH-INCOME NATIONS IN 2015

People in developed nations are living in the healthiest of all times. The advances in life expectancy in the 20th century and the beginning of the 21st century are remarkable by any standard. In spite of the paucity and unreliability of historical mortality data, experts agree that human life expectancy during the time of and before the Roman Empire did not

overcome the threshold of 30 years. The Industrial Revolution, however, changed radically the conditions of living and consequently generated a critical increase of longevity in industrial societies. Yet, by the beginning of the last century, life expectancy had been extended only 9 years, to an average of 37 years throughout the globe (Evans, 2001). The fastest and most unprecedented improvements in population health worldwide occurred in recent decades. Both adult and infant mortality decreased in every region of the world, and by the year 2015, global life expectancy had increased to over 72 years. It was just over 52 in 1960 (World Development Report database). To put this increase in context, it is sufficient to state that global life expectancy increased faster in the last 50 years than it did in the preceding 5,000 years.

Although many multiple factors contributed to this rapid and unprecedented rapid rise of life expectancy, by far the most important are the socioeconomic changes triggered by the Industrial Revolution. As clearly argued by McKeown, in a very famous project in the field of historical epidemiological in England and Wales, the largest proportion of the increased life expectancy did not occur because of healthcare improvements, but as a consequence of socioeconomic conditions (McKeown & Record, 1962) and related changes in nutrition, hygiene, and sanitation.

When considering the gross domestic product (GDP) per capita of the four case studies of this chapter, it is possible to see how in all countries rapid increases in GDP per capita occurred after the year 1800. As the Industrial Revolution originated in the United Kingdom, it provided a comparative advantage in terms of GDP per capita: In 1835, GDP per capita in the United Kingdom, Italy, United States, and Greece was \$3,786, \$3,338, \$2,660, and \$2,579, respectively. By the end of World War II, GDP per capita reflected a new distribution of power and wealth in the world, and it was affected by the destructive effect of the conflict especially in Europe. The GDP per capita in the United States reached \$16,401, in the United Kingdom it was \$11,574, while in Italy it was half that of 1939 at \$3,663 and \$2,147, respectively. Steady and rapid increases of GDP per capita occurred in all these nations after the war, although there was an abrupt end of this positive trend by the year 2008 at the outburst of the global financial crisis. In 2014, GDP per capita was \$51,664 in the United States, \$36,436 in the United Kingdom, \$32,829 in Italy, and \$22,344 in Greece.

The increase of GDP per capita since the Industrial Revolution, first experienced in the United Kingdom and then in the rest of the world, has generally been associated with improvements in health. In spite of numerous episodes of economic stagnation and recessions, world's life expectancy has increased steadily. The only two departures from secular trends towards better health in the last 50 years were experienced in the former Soviet Union and in sub-Saharan Africa in the 1980s. In more recent decades (the 1990s and after the year 2000), however, even these two regions restarted a pattern of health improvements enjoyed by the rest of the world.

In 2015, however, steady progress towards better health has surprisingly halted, and life expectancy started to fall in several high-income countries. A recent article analysing declines in life expectancy in 2014 by Ho and Hendi (2018) showed that declines occurred in 12 out of 18 high-income countries investigated. When examining updated information from the World Development Indicators database (accessed on July 8, 2019), it is possible to observe that 19 out of the 30 top economies in the world experienced declines in life expectancy at birth between 2014 and 2015. Such health reversals cannot be attributed to wars or new pandemics, though it is possible that socioeconomic changes such as the global financial crisis that began

in 2008 and austerity policies including budget cuts in healthcare and social welfare that were first introduced in 2010 may have exerted lagged effects on health and played a role in driving these declines.

Figure 2. GDP per capita (adjusted for inflation and price differences between countries and measured in international dollars in 2011 prices) in the United States, United Kingdom, Italy, and Greece.

When considering the four countries considered in this chapter, it is first interesting to note how their position changed substantially in the last half century. In 1960 life expectancy at birth was 71.12 in the United Kingdom, 69.77 in the United States, 69.12 in Italy, and 68.16 in Greece. By 2015, however, although there had been a reduction of longevity in all of these four countries, in the United Kingdom life expectancy in 2014 was 81.30 and went down to 80.95 in 2015, in the United States it moved from 78.84 in 2014 to 78.53 in 2015, in

Italy from 83.09 in 2014 to 82.54 in 2015, and in Greece from 81.38 in 2014 to 81.03 in 2015. In 2016, life expectancy stagnated in Italy and Greece and increased in most high-income nations (Ho & Hendi, 2018), but in the United States and United Kingdom it continued to decline.

The simultaneous reversal of life expectancy in high-income countries around the year 2015, after more than a century of steady increases, caught many epidemiologists by surprise. What can explain such a sudden change of direction in so many diverse, though economically developed, countries? In spite of the obvious national and cultural heterogeneity, are there common patterns of explanations that can help to understand mortality crises across high-income countries?

Source: World Development Indicators database (2018).

Figure 3. Life expectancy at birth in Italy, Greece, United Kingdom, and United States (1960–2017).

A variety of authors have provided different explanations for the health reversals in high-income nations that include the following:

1. Peak longevity
2. Rise of infant mortality
3. Deaths in old ages
4. Suicides and drug overdose in working-age men

Potential Explanations for the Decline

Peak Longevity

The search for the main determinants of the decline in life expectancy around 2015 in high-income countries should start from a simple question: Is it possible that “the human race has finally reached its biological limits of longevity?” Indeed, life expectancy cannot be expected to increase forever. The peak longevity hypothesis is worth further investigation; however, it is challenged by evidence of the relentless improvements of population health at the country and subpopulation level. First, longevity has increased beyond the average of most high-income nations and well beyond the longevity of the United States (79 years) and the United Kingdom (81 years) in many countries. It is sufficient to state that in 2017 life expectancy at birth reached 85, 84, and 84 years in Hong Kong, Japan, and Switzerland, respectively. Second, in the best performing countries and population groups that achieved exceptional levels of longevity, life expectancy continues to improve, and there is no indication of slowing down (Christensen, Doblhammer, Rau, & Vaupel 2009; Jasilionis & Shkolnikov, 2016; Oeppen & Vaupel, 2002). The most important causes of death, heart diseases and malignant neoplasm, are still in steady decline in most high-income nations.

Data from the WHO Mortality database clearly show that standardised mortality for all cancers have been reducing in United States, United Kingdom, and Italy, and only in Greece it has started to rise since 2011. More importantly, recent advances in longevity and reductions in mortality occurred in most age groups, including the elderly and those aged more than 80 years (Christensen et al., 2009).

In spite of the impressive improvements in health achieved in the last decades, evidence seems to indicate that there is still some room for improvement in health in the healthiest and most advanced economies.

Rise of Infant Mortality

Some authors indicate that infant mortality may be a possible culprit for the reduction in life expectancy in high-income nations around 2015. Recently, the Office for National Statistics (2018) warned against the worrisome rise of infant mortality rate in England and Wales since 2014 and highlighted that it especially affected the poorest and underserved communities. Indeed, after a steady decline since the 1980s, infant mortality increased from 3.6 deaths per 1,000 live births in 2014 to 3.8 deaths per 1,000 live births in 2016.

Recent deteriorations in child health have not only been experienced in the United Kingdom, but even more worrisome trends occurred in Greece where infant mortality rate sharply increased from 3.2 per 1,000 live births in 2011 to 4.3 per 1,000 live births in 2017. According to a study based on the Global Burden of Disease (GBD), the under-5 mortality rate in Greece has increased especially in connection with deaths due to neonatal hemolytic disease and neonatal sepsis in children younger than 5 years (GBD Study Collaborators, 2018). Numerous authors have attributed such trends not only to the effects of the global financial crisis, but also to the application of austerity policies that have generated important changes in the quality and accessibility of healthcare services for maternal and child health.

Figure 4. Infant mortality rates (per 1,000 live births) in Greece, Denmark, France, Portugal, and Czech Republic (2000–2017).

When considering other high-income nations, however, apart from the discrepancy between data in infant mortality between ONS and the World Development Indicator (WDI) in the United Kingdom (the former indicates an increase of infant mortality while the latter a decrease from 3.8 to 3.7 per 1,000 live births), the case of Greece is really exceptional. In most high-income nations, between 2014 and 2017, infant mortality continued to decrease, and it increased slightly (0.1 per 1,000 live births) only in four additional advanced economies: from 3.6 to 3.7 per 1,000 live births in Denmark, from 3.4 to 3.5 per 1,000 live births in France, from 3.0 to 3.1 in Portugal, and from 2.5 to 2.6 per 1,000 live births in the Czech Republic. In the United States and Italy, infant mortality reached a plateau at 5.7 deaths per 1,000 live births and 2.9 deaths per 1,000 live births in 2016, respectively.

Worsening Elderly Health

Another hypothesis for the decline of life expectancy in 2014 regards the worsening health status of the elderly population. Evidence from the United Kingdom has shown that the population over 65 years old have borne the brunt of deceleration in life expectancy gains and may be the key reason for the decline after 2015 (Hiam, 2018). Indeed, research shows that an increase of premature deaths in the population over 65 years in 2014–15 has been experienced in several European countries (European Monitoring of Excess Mortality for Public Health Action, 2016).

A recent article by Ho and Hendi (2018) indicated that the increasing mortality in older ages was associated with deaths due to respiratory diseases in the same year. In 2014–2015 there was a particularly severe influenza season that may have put old people at higher risk of mortality, especially those affected by Alzheimer's disease and other nervous system disorders and cardiovascular diseases. Cold weather has also been cited as one of the potential causes for the increase of mortality in England in 2015 by another study (Newton et al., 2016). As noted by Hiam, Dorling, Harrison, & McKee (2017), however, winters in most high-income countries have become progressively milder in the last few years due to climate change, and in the same years there has also been a decrease in funding to healthcare and social welfare programmes (Green, Dorling, Minton, & Pickett, 2017).

Other drivers of the increase in old-age mortality include circulatory diseases, Alzheimer's disease, mental disorders, and other problems of the nervous system. Yet, research seems inconclusive in establishing whether the generalised decline in 2015 was driven by any particular cause-specific mortality increase among the elderly. Moreover, according to Ho and Hendi, 2018, the declines in life expectancy across selected high-income nations were gender-specific and some countries did not experience them at all: Finland, Japan, Australia, Norway, Canada, and Denmark. The only two countries that experienced declines in life expectancy for two consecutive years, both in 2015 and 2016, were the United States and the United Kingdom. It is possible, as admitted by the authors of the analysis, that contributing factors for the decline of life expectancy in 2015 may include socioeconomic inequality, and erosion of social protection may have played a role in elderly health and these mortality crises.

Drug Overdose in Working-Age Men

Some authors have highlighted the importance of declining health status in working-age men as the key explanatory factor for the rise of mortality in 2015. Numerous reports indicate that the decline of life expectancy in the United States and a major reason for its poor health

performance in the last decades include a sharp rise of drug overdose (Barbieri, 2018; Ho & Hendi, 2018). Indeed, the number of deaths due to drug overdose in the United States rose from 16,849 in 2000 to 70,237 in 2017 (Centers for Disease Control and Prevention [CDC] Wonder Online database, 2019). This rapid increase is exceptional by any standard, and the United States, with about 4% of the world's population, has now approximately 33% of the world's drug overdose deaths.

Figure 5. Total number of deaths due to drug overdose among all ages, by gender in the United States (1999–2017).

Although deaths due to drug overdose can be a key contributor for the decline of longevity in the United States, it does not seem to be as important in other high-income nations. According to a report by Public Health England, drug misuse among younger people has been mentioned as one of the causes for the decline in life expectancy in the United Kingdom in 2014 (Hawkes, 2018), and indications of recent increases of drug overdose have also been recorded in Australia and Canada. Yet, these figures remain far below and not comparable to that experienced in the United States (Ho & Hendi, 2018). Using the Human Mortality Database of the World Health Organization (WHO), Barbieri (2018) conducted a cross-national analysis of twelve high-income countries to estimate the contribution of drug-related deaths to explain the US disadvantage in mortality. Results showed that drug-related deaths contributed to about 40% of the US disadvantage in mortality among working-age men. However, they also showed that the exceptional increase in drug-related deaths was specific to the United States only and not very relevant to explain the mortality crisis of 2014 other high-income nations.

The Need for a Comprehensive Approach in the Study of Mortality Crises

There is a substantial degree of heterogeneity in the identification of plausible factors behind the 2015 mortality crisis in high-income countries: In Greece, there has been a significant rise of infant mortality rate, in England and other European nations the decline in life expectancy seems attributable to a worsening of health conditions among the elderly, while in the United States the role of drug overdose seems having played an important role

compared to other countries. Further research is needed to investigate the factors that led to a concomitant mortality crisis in 2015. On the one hand, it is necessary to investigate the causes of the causes of such mortality crises including socioeconomic changes and policies. In the United States, several authors have studied the decline in life expectancy in the context of the so-called deaths of despair, which, in turn, have been associated with policies of de-industrialisation, the rise of income inequality, and the socioeconomic decline affecting middle-aged White Americans. In Greece and the United Kingdom, researchers have contextualised the rise of infant mortality and old-age mortality, respectively, to austerity policies and budget cuts that have undermined important social and health services, disproportionately affecting the most underserved populations in both countries.

While investigating the political and contextual determinants of recent mortality crises, it is equally important to investigate the protective effects of reforms and to understand why some countries have not experienced mortality crises in 2015. Possible reasons may include stronger social protections, higher levels of social cohesion and social support, and lower levels of economic inequality.

**‘THE LIBERALISATION OF DESPERATION’:
THE RISE OF SUICIDES, ALCOHOL DEATHS, AND DRUG
OVERDOSES AMONG MIDDLE-AGED WHITE AMERICANS
AFTER TRADE LIBERALISATION POLICIES IN 2000**

The decline in life expectancy among so many high-income nations in 2015 raised several questions for researchers, along with hypotheses on mechanisms explaining why the United States lags behind other advanced economies in terms of longevity. Since the mid-1980s, the United States experienced a slow increase in life expectancy at birth compared to other high-income nations and now ranks below nations with much lower GDP per capita such as Portugal (81.12 years), Cuba (79.92 years), and the Czech Republic (79.47 years). What can explain the poor health record of the United States and such progressive deterioration of the US position in terms of health since the mid-1980s?

There are several explanations in the literature for the slower declines in mortality of major causes of death in the United States compared to other nations. Except for cancer mortality, which is lower in the United States than in other high-income nations, all causes of death seem to contribute to this health gap. As shown by Wilkinson and Pickett (2009), when compared to other rich nations, the United States performs quite poorly in a long list of health and social indicators including obesity and diabetes, infant mortality, mental health disorders, homicide, and economic and political determinants of health such as inequality, social distrust, access to healthcare, and access to education and social safety nets (Wilkinson & Pickett, 2009). However, a key health indicator that distinguishes the United States from other advanced economies is the sharp rise of mortality rates among White men aged 35–64 years around the early 2000s (Barbieri, 2018). In a widely publicised paper, Case and Deaton surprised the world of epidemiology by highlighting the fall of life expectancy among middle-aged White men as the only demographic group experiencing a mortality crisis in the United States and other high-income nations (Case & Deaton, 2017). This trend is exceptional

not only because it did not affect other nations and other underserved ethnic groups such as African American and Latinx populations, but also because the causes of deaths leading to the mortality crisis in the United States clustered around the determinants of psychosocial stress and mental health outcomes: suicides, alcohol-related deaths, and drug overdoses (Garcia, 2017). Some authors have called these cases “deaths of despair.”

What is behind the rise of suicides, alcoholism and chronic liver diseases, and drug abuse (or poisoning) among middle-aged White men since the early 2000s? Why are these mortality trends different among other ethnic groups such as African American and Latinx? In order to address these questions, it would be useful to first examine the different determinants of the deaths of despair in a coherent sequence of distal economic and political factors (e.g., globalisation, trade liberalisation, delocalisation, and decline of manufacturing industry, unemployment, and increasing income inequality) and proximal determinants (e.g., psychosocial stress, meaninglessness, sense of unfairness, and psychological resilience).

Distal (Economic and Political) Determinants

A rapid rise of deaths due to alcohol, suicides, and drug overdose does not occur in a vacuum, but it is often the result of upstream changes or societal level variations that may often involve other psychosocial mediators such as stress, depression, hopelessness, and meaninglessness. However, these variations are often connected to trends or policy changes that profoundly affected society, social relations, and individuals. Several authors have suggested that the rising rates of suicides and overdose among middle-aged White Americans may be attributable to the declining socioeconomic conditions of the working class due to an epidemic of job losses caused by labour market changes deriving from globalisation and trade liberalisation policies in the early 2000s.

Globalisation and Trade Liberalisation Policies

During the last four decades, there has been an acceleration of social, economic, and political change worldwide. Globalisation was supposed to bring about positive changes including higher living standards, higher access to goods and services, wider freedom of choice, and even better health conditions. However, some of these changes have also caused adverse consequences, especially in populations whose ability to adjust to the new circumstances was limited. Policies of globalisation and market deregulation, defined as the “degree to which market forces are allowed to operate without interference from outside intervention, especially in the form of government ownership, regulations and taxes” (De Vogli, 2013) have produced not only sharp increases of income inequality, but also changes in the labour market affecting the employment and job security of millions of families and workers.

Particular importance for the rise of mortality due to suicides, alcohol and drug-related deaths in the United States must be given to a specific type of globalisation and market deregulation policy: trade policies. Since the creation of the General Agreement on Tariffs and Trade (GATT) in 1947, economic growth has historically been the rationale and the justification behind trade liberalisation—the reduction of trade barriers such as tariffs, quotas, and import taxes—and the development of new free trade agreements (FTAs) (Khan, Pallot,

Taylor, & Kanavos, 2015). Trade liberalisation policies that increase export opportunities to foreign markets, lower the cost of imported goods, and attract foreign investment can, in theory, promote economic growth (Chang, 2002). Income generated from trade policies may, in turn, lead to better health given the historical link between GDP per capita and life expectancy across nations.

However, the impact of trade policies on population health largely depends on their distributional effects: Income-generating reforms can lead to better health to the extent that such income “trickles down” to the lowest socioeconomic strata of the population and reduce economic inequality. Trade liberalisation policies have been found to create a few “winners,” such as large transnational corporations (TNCs) that exploit lower tariffs abroad and delocalise production in countries where labour is cheaper, and far too many “losers,” such as low-skilled workers (EPHA, 2015; McNamara, 2015; Ottersen, 2014). Evidence from the North American Free Trade Agreement (NAFTA), for example, showed that it facilitated the penetration of TNCs into foreign markets, but reduced employment and wage levels in the United States especially in the manufacturing sector (Scott, 2003). Some authors, however, downplay the role of trade policies in the increase of inequality. Helpman and Limao (2016), for example, conducted a recent literature review and concluded that globalisation and trade policies explain only a fraction of increased inequality, which is largely due to an increase in the wages of low-skilled workers (which is expected to produce positive health effects on such populations). Pavcnick (2017) focused on low- and middle-income countries and reached similar conclusions, emphasising that, although the association between trade policy and inequality is real, it depends on contextual factors such as the mobility of workers and capital across firms, industries, and geographic locations.

The proposed connection between trade policies and the rise of deaths due to suicides, alcohol use, and drug overdose since the year 2000 sounds like mere academic speculation. Yet, a few studies have already found empirical support for the hypothesis and identified a plausible relationship between macro-level economic and political factors and the deaths of despair in the United States. Pierce and Schott (2018) showed that US counties exposed to exogenous changes in international trade policy have experienced sharper increases in fatal drug overdoses, especially among Whites. According to these authors, the starting point of this epidemic of deaths of despair was October 2000, when the United States passed a bill granting permanent normal trade relations (PNTR) with China, eliminating the need for annual renewals of a policy of low tariffs between the United States and China and rendering production in China for export to the United States easier and more attractive than ever before. Although employment opportunities for low-wage workers have been declining before this trade policy, PNTR seems to have played a key role in the rise of the deaths of despair because its effects were abrupt, creating reallocation of large number of workers in a short period of time, and long-lasting at the same time. Hollingsworth (2017) found that macroeconomic changes at the county and state level were associated with increases in deaths and emergency room visits due to opioid overdoses. Another study by Adda and Fawaz (2016) showed that in areas with larger increases in import competition there were increased mortality and worsening of health indicators. Clearly, it is possible that the job losses experienced in the United States that led to the epidemic of deaths of despair can be attributable to other factors, not only to the passage of the PNTR. A recent paper by Handley and Limao (2017) emphasised the importance of China’s accession to the World Trade Organization (WTO) in 2001 which (together with other factors such as the particularly

favourable low exchange rate of the Chinese Yuan) may have improved competitiveness of Chinese goods and their successful export growth to the US market.

Labour Market Changes, Job Losses, and Job Insecurity

The first mechanism by which globalisation and trade liberalisation policies increased the deaths of despair is through changes in the labour market such as an increase of short-term employment, changes of labour types, reallocation of workers or career changes, and changes of regulations regarding workers' security and right. A study by Sullivan and Wachter (2009) found that mass layoff experiences were associated with a sharp increase in the probability of death among high-tenure workers. Browning and Heinsen (2012) and Classen and Dunn (2012) showed that employment duration mediated the association between job loss and deaths of despair.

Research showed that changes in labour force participation, especially in the manufacturing industry, have been pivotal in mediating the relationship between trade liberalisation policies and the rise of deaths of despair (Pierce & Schott, 2018). Autor (2014) found that workers with greater exposure to imports from China exhibited a stark decline in relative earnings. Of course, the reduction of employment in the manufacturing industry (Krueger, 2017) after trade liberalisation policies has been exacerbated by the outbreak of the 2008 global financial crisis. Such changes have disproportionately affected less educated Whites living in suburban areas, smaller cities, and rural areas in the heartland of the United States. There was a dramatic reduction of the number of private-sector manufacturing employees, from 19,167 million in 2000 to 13,251 million in 2010, for a total of almost 6 million jobs lost, mostly to China.

Figure 6. Number of private-sector manufacturing employees in the United States from 1985 to 2018 (in thousands) after the US-China free trade agreement in 2000.

All these economic stressors took a heavy toll on White Americans. Unemployment is a serious risk factor for poor health not only because it is associated with decreased access to basic material items, housing, healthcare, and education, but also for its psychosocial effects. According to Amartya Sen (1997), who was awarded a Nobel Prize in economics, unemployment generates psychological harm because of loss of self-confidence, disruption of social role, anxiety about the future, sense of exclusion, and disruption of family and social relations. Unemployment can also be associated with social isolation and social exclusion. Researchers have found that unemployment correlates with a long list of adverse health effects including suicide, psychiatric morbidities (Ferrie, 2001), high blood pressure, and the onset of an array of different diseases (Catalano, Rook, & Dooley, 1986). The loss of emotional balance caused by unemployment seems also to be a major risk factor in the adoption of health-damaging behaviours such as alcohol consumption (Catalano, Dooley, & Wilson, 1993).

Another possible effect of globalisation and trade liberalisation is job insecurity. Job insecurity is a powerful chronic stressor because it increases life and economic uncertainty especially among low-skilled workers. For young people, it is a major obstacle for having a stable life, a marriage, vacations, and choices. Job insecurity makes also people more likely to change residence and disrupt family life and the pattern of social relationships that buffer them against stressful life situations. A group of social scientists investigated the health effects of job loss and insecure reemployment among white-collar civil servants after the privatisation of public services in England. According to their findings, insecure reemployment was associated with increases in minor psychiatric morbidities and with having four or more consultations with a general health practitioner in the last year, independent of financial strains and health behaviours (Ferrie et al., 1998). A recent study examined changes in the health status of civil servants whose employment security was threatened. A study of the effect of job losses resulting from a factory closure found that health began to deteriorate when redundancies were first announced, before people became actually unemployed (Beale, 1998). Job uncertainty has also been associated with a variety of adverse mental and physical health outcomes. Ferrie and colleagues (2002) found that loss of job security has adverse effects on self-reported health and minor psychiatric morbidity, which are not completely reversed by removal of the threat and which tend to increase with chronic exposure to the stressor. With regard to health behaviours, some studies reported higher unhealthy behaviours among people employed in insecure jobs (Domenighetti, D'Avanzo, & Bisig, 2000).

Increasing Income Inequality and Downward Social Mobility

Some authors have maintained that the epidemic of deaths of despair is associated with growing social deprivation for the most disadvantaged groups and growing economic inequalities. A number of studies have tried to explain the surprising trend of increasing mortality among Whites in the United States by focusing on “fear of downward social mobility” (Cherlin, 2016) and “inequality of opportunity” (Chetty, 2014). A corollary of this conceptual framework is the hypothesis of cumulative disadvantage for less educated workers, that is, the decline of their wages, social status, and purchasing power and a parallel increase in economic power in the top income brackets at the same time.

Since the early 1980, with the advent of neoliberalism, there have been increasing economic inequality in the United States and most high-income countries and a progressive

erosion of the purchasing power of the middle classes. These trends may have created a set of frustrating and stressful patterns, especially among low-educated Whites, as widening economic disparities distanced them from the most fortunate White reference points in higher social classes. According to Richard Frank, as inequalities widen, and the top earners set new standards in the pattern of material well-being and conspicuous consumption (e.g., bigger houses, bigger cars), the rest of society is forced, especially those who view them as “reference points,” to engage in “defensive spending” to maintain relative status (Frank, 1999). Earning enough extra income to keep up with the rising levels of conspicuous consumption becomes more and more important as standards of living rise and social comparison may create status anxiety. It is possible that White Americans have been disproportionately affected by status anxiety for the sense of entitlements given by their ethnicity and therefore have been hit most severely by the erosion of their socioeconomic conditions.

In an editorial published in the *New York Times*, Cherlin (2016) asked the question, “Why are White deaths rising?” Reference group theory may help. White Americans may be comparing their conditions against prior generations of working-class Whites, who fared better in terms of employment opportunity and wages. This comparison may make them feel worse off. Conversely, minorities may compare themselves against prior generations who had fewer opportunities, and this may make them feel better off (Monnat, 2017). African Americans and Latinx may feel a sense of progress that resonates with the natural inclinations of people to improve their own status. Whites may, on the other hand, feel that their status is getting worse.

Note that during the years of increasing inequality in the United States, while gaps in educational achievement and proficiency have widened across income groups, they have narrowed between minorities (Blacks and Latinx) and Whites (Porter, 2015; Reardon & Portilla, 2015). Inequality in life expectancy between Blacks and Whites have moved from 7 years in 1990 to 3.4 years in 2014 (Case & Deaton, 2017; Tavernise, 2016). These figures indicate a special, unique type of effect of policies on White Americans. The relationship between inequality and frustration, unhappiness, and anger of White Americans was highlighted after the 2016 US election of Donald Trump. A study found that in those US counties where a higher percentage of deaths of despair have occurred, there has also been a higher proportion of votes for Trump (Monnat, 2016). Another study showed that these areas are also disproportionately affected by high levels of inequality and unemployment, especially jobs lost in the manufacturing industry.

Proximal (Psychosocial) Determinants

Chronic Stress, Status Anxiety, Social Exclusion, and Powerlessness

A key mediator between trade liberalisation, job loss, and deaths of despair is stress. Although stress is largely related to objective stressors in the environment, perceived stress is mediated by people’s appraisal of the external situations. When confronting socioeconomic stressors, people evaluate whether these demands pose a potential threat (primary appraisal) and whether sufficient adaptive capacities are available to cope with them (secondary appraisal). If they find the socioeconomic demands taxing or threatening, and at the same

time view their coping resources as inadequate, they perceive themselves as under stress. The negative appraisal of stress may result in negative emotional states such as anxiety, loss of self-esteem, and powerlessness. It may also affect the deeper feelings of individuals including life purpose (Cohen, 1997).

Researchers have identified marked differences in terms of stress, worrying, and anger between Whites and minorities (Graham, 2017). White Americans, in spite of their higher life expectancy and better material conditions, are in general worse off in terms of mental health indicators such as depression, anxiety, and suicides than African Americans (Assari & Lankarani, 2016). The former group performs poorly across most psychosocial factors, indicating a high level of distress and hopelessness at all income levels. Reasons explaining why Whites have higher level of stress than minority counterparts include lower levels of resilience and poorer coping strategies.

When confronting stress such as being fired, individuals evaluate their resources to determine whether they can cope with the situation. Coping strategies refer to the specific efforts, both behavioural and psychological, that people employ to master, tolerate, reduce, or minimise stressful events. Two general coping strategies have been distinguished: actions designed to directly alter the threatening conditions (e.g., flight or fight) or thoughts or actions whose goals are to relieve the emotional stress response such as cognitive restructuring and denial of danger (Cohen, Underwood, & Gottlieb, 2000). When stressors exceed the adapting capacity of an individual to deal with it and coping strategies are unsuccessful, the results are psychological states associated with poor health and unhealthy behaviours such as hopelessness, learned helplessness, and powerlessness (Syme, 1991), or the belief that an individual cannot determine the occurrence of outcomes (Seeman, 1959).

Stress-Relieving, Self-Destructive Behaviours

When people are affected by chronic stress and status anxiety, certain behavioural responses such as alcohol consumption and drug use may be viewed as having perceived adaptive benefits in the short run as stress relievers, although in the long run they will produce damaging effects (McEwen & Seeman, 2000). In a sense, they are acts of self-medication. Under the influence of economic problems, stressful social and physical environments, low job satisfaction, unemployment or the threat of unemployment, and lack of influence and control over one's life, the individual is more likely to adopt poor health behaviours. These behaviours are functional because they may give short-term relief in a stressful situation. In constrained economic circumstances, alcohol and drug use can be one of the few activities undertaken for personal pleasure and one that provides some respite from the strain of coping with the consequences of material deprivation and status inferiority (Davey-Smith, 1996).

Lack of Sense of Purpose/Meaninglessness

Researchers have found that an important determinant of health is meaning in life and an overall sense of coherence that life makes sense. People are more likely to cope and succeed in dealing with stressors if they possess a positive motivational state, a determination to meet personal goals and a will to survive under adverse social, economic, and political conditions. Exposure to adverse circumstances of life, together with unsuccessful coping strategies and learned powerlessness, however, can lead to depression and a sense of meaninglessness. Lack of purpose in life, or the lack of belief that life provides suitable challenges and rewards, such

that life continues to be worth living, has been associated with poorer health outcomes and self-destructive behaviours (Antonovsky, 1979; Burton, 1988).

Socioeconomic stressors can make people question the meaning of their life through uncertainty and loss of control. Sense of purpose can also be lost when people lose their social roles (social integration) and lose social bonds (social control). Stressors—whether social, economic, or political—make it more difficult to predict the future. This uncertainty means that it is difficult for anyone to set out where they expect to be in 5 or 10 years' time. This raises particular difficulties for individuals and families. This affects people's ability to plan their life and their vision of the future. Loss of purpose in life can even increase the risk of suicide or affect a person's motivation to adopt healthy behaviours (Cohen et al., 2000).

Social Exclusion and Social Support

A possible mediator between changes in labour market, declining social status, and the rise of deaths of despair is social exclusion. Social integration is the extent to which an individual participates in a broad range of relationships. Those who participate in a social network are subject to social controls and peer pressures that influence normative health behaviours. Integration in a social network is also presumed to provide a source of positive effects such as self-worth because of demonstrated ability to meet normative role expectations. These positive psychological states are presumed to be beneficial because they reduce psychological despair, result in greater motivation to care for oneself, or result in suppressed neuro-endocrine response and enhanced immune function. Having a wide range of network ties also provides multiple sources of information and thereby increases the probability of having access to an appropriate information source. Information could influence health-relevant behaviours or help one to avoid or minimise stressful or other high-risk situations. Being part of a large social network may also operate to prevent disease by providing tangible and economic services that result in better health and better healthcare for network members (Cohen et al., 2000).

The feeling of being ostracised by the rest of society because of declining social status and loss of employment produces shame, depression, anxiety, anger, and a sense of alienation, and it decreases feelings of control and self-esteem. Social exclusion, or inadequate participation in a society's structure of opportunities, can interact with other socioeconomic stressors in determining self-damaging behaviours. Acquisition of core social roles, such as the work role, the family and marital role, and civic roles, contribute to self-regulation in adult life, strengthening a sense of self-esteem, self-efficacy, and belonging (self-integration). It is argued that exclusion from or loss of core social roles impairs personal self-regulation and triggers a state of "social reward deficiency." This state, in turn, elicits prolonged stressful experience, and it may reinforce a person's craving for stress-relieving, potentially addictive health-damaging behaviour. In extreme cases, it may lead to suicide (Siegrist, 2000).

Social support can also protect individuals against stressful events by preventing a particular situation from being appraised as highly stressful. The belief that others will provide necessary resources may redefine the potential for harm posed by a stressful situation. Support beliefs may reduce or eliminate the affective reaction to a stressful event, calm the neuroendocrine system, dampen physiological responses to the event, or prevent maladaptive behavioural responses (Cohen, 1989).

Psychological Resilience

Resilience refers to an individual's ability to adapt to stressful circumstances and remain healthy in spite of adversity. The increase of mortality due to suicides, alcohol use, and drug overdose among only White Americans raises several questions on the characteristics that make them less resilient than minorities when facing adverse circumstances. Researchers found that Whites not only have a higher proportion of mental health disorders and higher level of unhappiness, but also are less optimistic and more hopeless compared to African Americans and Latinx (Graham, 2017).

There may be several reasons why African Americans and Latinx are more resilient than Whites. First, minorities that used to be disproportionately exposed to history of deprivation and structural injustices may be better equipped in coping with adversity because they have more experience of it (Assari & Lankarani, 2016). In this regard, the role of expectations seems particularly important: White Americans expecting a higher status and better treatment in society may make them disproportionately at risk of stress and frustration. This explanation relies on what has been called "happy peasant, frustrated achiever" effect. As Paul Krugman, who was awarded a Nobel Prize in economics, once noticed, "we are probably referring to individuals who were raised to believe in the American Dream and are coping badly with its failure to come true" (Krugman, 2015).

A second potential reason may be the differential impact of labour market disruption and stronger competition for fewer jobs intensified by trade liberalisation policies and the global financial crisis. Such changes have made less educated Whites worse off, relatively speaking, compared to their minority counterparts. Paradoxically, the disappearing manufacturing jobs that contributed to the decline of social status among Whites may have resulted in minorities gaining ground and reduced the social gap between them and Whites. Researchers have found that both absolute income and relative social status relate to health.

A third possible explanation is that minorities may have access to stronger social support and social cohesion. Social cohesion refers to those features of social organisations such as networks of associations, high levels of interpersonal trust, and norms of mutual aid and reciprocity that act as resources for individuals and facilitate collective action (Coleman, 1990; Putnam, 1993). A large body of evidence shows that social cohesion is strongly related to mortality and other health indicators (Kawachi & Berkman, 2004). A county-level study showed that areas with higher levels of social cohesion experienced lower mortality rates for suicides, alcohol use, and drug use (Monnat, 2017) than areas characterised by low social connectedness or what some sociologists called "civic deserts." Latinx communities have been singled out in epidemiology for their high level of cohesion and strong social relations in what some have defined as the "Health Latino paradox" (Franzini, Ribble, & Keddie 2001). The role of community may also be a protective factor in African American lives, too.

Finally, minorities have been reported to be more religious than their White counterparts. Spirituality has been identified as an important factor in reducing the impact of stressors on health status. Religion and spirituality are possible stress-buffering mechanisms that reduce self-destructive behaviours (e.g., suicide, alcohol abuse) because they fulfil the functions of finding a meaning and purpose to life, and bind people together. Protective factors such as participation in community activities and religious attendance therefore play key roles in modifying the negative relationships between exposure to stressors such as unemployment and financial strain (Chatters, 2000) due to trade liberalisation policies and de-industrialisation.

‘ECONOMICALLY SUICID(ED)’: THE MENTAL HEALTH MORTALITY CRISIS IN THE UNITED STATES AND EUROPE AFTER THE 2008 GLOBAL FINANCIAL DOWNTURN AND AUSTERITY POLICIES

In the search of the putative causes of the decline in life expectancy among high-income countries, including the United States, United Kingdom, Italy, and Greece, some authors have highlighted the role of austerity policies and budget cuts in healthcare and social protection following the 2008 global financial crisis. Before examining the health effects of austerity and the economic crisis, it is necessary to analyse why austerity policies have been the implemented and the underlying causes of the global financial downturn.

The Causes of the 2008 Global Financial Crisis

In 2008, the world was hit by one of the worst economic recessions since the 1929 Great Depression. The outbreak of the financial downturn originated in the United States with the crisis of subprime mortgages, including infamous NINJA (no income, no job, no assets) loans or high-interest loans given to otherwise unqualified individuals. These loans, that often included low interest rates that increased sharply after an initial period of time, were sold to Wall Street investment banks that pooled them and repackaged them into “mortgage-backed securities” (securitisation). The proliferation of these securities tied to subprime mortgages created a “housing bubble” that eventually burst after many of those who had taken risky loans were unable to meet the loan repayments, creating panic in the global market and the bankruptcy of big banks like Lehman Brothers.

According to the Financial Crisis Inquiry Report of the Financial Crisis Inquiry Commission (2011), the “crisis was avoidable” and its major causes included:

1. Collapsing mortgage-lending standards and the mortgage securitisation pipeline
2. Over-the-counter derivatives
3. Excessive borrowing, risky investments, and lack of transparency
4. Dramatic failures of corporate governance and risk management at many systemically important financial institutions
5. Government that was ill-prepared for the crisis and delivered an inconsistent response
6. Failures of credit rating agencies
7. Widespread failures in financial regulation and supervision
8. Systemic breakdown in accountability and ethics

Although all these factors have importantly contributed to the Great Recession, it is also important to highlight the root causes of the downturn, including the policies and ideology that promoted financial deregulation and indiscriminate capital mobility in the last four decades. Using data on temporal trends in the frequency of banking crises over the last century in connection with an index of international capital mobility in the same period from Kaminsky and Reinhart (2008), it is possible to observe that both the 1929 Great Depression

and the 2008 Great Recession were anticipated by years of speculation, indiscriminate capital flow (Kaminsky & Reinhart, 2008), and excessive deregulation of financial markets. Just to put things into perspective, in 2007 mortgage-backed securities had risen to \$3 trillion (Johnson & Kwak, 2010), while credit-default swaps reached over \$50 trillion (Tett, 2009). In 2010, the total volume of off-exchange trading of financial derivatives, which Warren Buffet once called “financial weapons of mass destruction,” was estimated at \$601 trillion (Central Intelligence Agency, 2013). The world GDP in the same year was about 70 trillion.

Evidence shows that the frequency of banking crises was very low during the postwar period (1945–1971), a time characterised by low levels of capital mobility worldwide due to effective capital controls and regulations of the Bretton Woods System. The dismantling of this global system of regulations under the influence of the neoliberal ideology and the myth of the “self-correcting market” that guided national and global policies since the late 1970s, however, made the world at higher risk of financial instability and vulnerability to crises.

Global and national deregulation policies have also increased inequality both nationally and internationally. Historical trends from 1910 to 2010 show that peaks of excessive deregulation of financial markets and indiscriminate capital mobility coincided with the times when the highest percentage of total income went to the top 1% of the population in the United States (De Vogli, 2013b). The two most notable peaks are the Great Depression in 1929 and the Great Recession in 2008.

This may be no more than mere coincidence; however, there are plausible explanations to regard inequality as a determinant of financial instability. On the one hand, inequality may be a precondition of overspending and consumer indebtedness in low- and middle-income populations. On the other hand, high inequality may be associated with over-investment in short-term financial profiteering among the very wealthy, a precondition of price distortions and asset bubbles. Even economists associated with the International Monetary Fund (IMF) argued that there is a connection between inequality and financial instability and highlighted the importance of “restoring the bargaining power of low income groups as the most effective strategy to prevent future economic meltdowns” (Kumhof & Ranciere, 2011).

The Socioeconomic Effects of the Crisis: Unemployment, Poverty and Inequality

The crisis spread from the United States to the rest of the world and from the financial sector to the “real economy.” Europe was hard hit in 2010 by the so-called sovereign debt crisis that began in Greece when the new government revealed that previous administrations (helped by investment bank Goldman Sachs) had been misreporting budget data. From Greece the crisis spread to other European economies, especially those with a high debt over GDP ratio, or what The Economist magazine called the PIIGS: Portugal, Ireland, Italy, Greece, and Spain.

The effects of the crisis included millions of jobs lost, countless foreclosures, increased poverty, reduced spending and consumption, and the bankruptcy of innumerable banks and companies. According to the International Labour Organization (ILO), since 2007, worldwide unemployment has increased by more than 67 million people due to the crisis (ILO, 2013). At the same time, about 60 to 100 million people have been pushed into severe poverty (ILO, 2010). Male workers were particularly affected by the crisis and job losses. Greece was the hardest hit: The Greek male unemployment went from 5.14% in 2008 to 24.51% in 2013! Italy, too, experienced a severe male unemployment crisis that increased from 5.5% in 2008

to 11.86%. In the United States, male unemployment changed from 6.09% in 2008 to 10.55% in 2010. In the United Kingdom, it grew from 6.06% in 2008 to 8.56% in 2010.

Source: World Development Indicators database (2018).

Figure 7. Male unemployment rate in Italy, Greece, United Kingdom, and United States (1991–2018).

Some authors have claimed that crisis and austerity produce regressive effects and have widened economic gaps both in Europe and in the United States (De Vogli, Kouvonen, & Gimeno, 2014; Piketty & Saez, 2014). When looking at the World Development Indicators (WDI) database, it is possible to notice that the Gini coefficient has increased in all four countries, but with some important differences. In Italy and Greece, it increased sharply. In Italy, the Gini index rose from 33.0 in 2007 to 35.5 in 2015, while in Greece it increased from 34.0 in 2007 to 36.0 in 2015. In the United States and the United Kingdom, the Gini index increased only slightly, from 41.0 in 2007 to 41.1 in 2016 in the United States and 33.0 in 2007 to 33.1 in 2015 in the United Kingdom.

The Mental Health Crisis: The Rise of Suicides and Mental Illnesses

After producing important economic and social consequences, the crisis resulted in changes in the health status of entire populations worldwide. Since 2008, suicides have increased in the United States and the Eurozone. A study conducted by Reeves and colleagues (2012) estimated that during the recessionary period after 2007, there were an estimated 4,750 excess suicide deaths in the United States alone. In Europe, as already pointed out by previous authors (Stuckler, Basu, Suhrcke, Coutts, & McKee, 2009a), standardised death rates for self-inflicted injuries increased in the years of the crisis reversing a decade of steady decline before 2007.

In the UK, between 2008 and 2010, there were an estimated 846 more suicides among men and 155 more among women than expected based on historical trends (Barr, Taylor-Robinson, Scott-Samuel, McKee, & Stuckler, 2012). In Greece, a country hard hit by the crisis, suicides have increased by 17% from 2007 to 2010 (Kentikelenis et al., 2011). Moreover, there was a 40% rise in the first half of 2011 compared with the similar period in 2010, with suicide attempts significantly elevated among persons with high scores of economic distress (Economou, 2011). In Italy, another country heavily affected by the Great Recession, a new study updating previous analysis on excess deaths due to suicides attributable to the crisis (De Vogli, Marmot, & Stuckler, 2012) showed that there were 1,251 and 123 excess suicides due to the economic crisis in men and women, respectively (De Vogli et al., 2019). Most of these excess suicides due to the crisis were attributable to a single age group: men from 45 to 64 years of age.

The crisis increased not only suicides but also mental health outcomes. A cross-national study in the United States and 13 European countries found that job losses among 50- to 64-years-olds were associated with a 28% and 8% increase in depressive symptoms in the United States and Europe, respectively (Riumallo-Herl, 2014). A study from Italy showed that the fall of GDP per capita and the rise of unemployment following the 2008 financial crisis resulted in a sharp increase of deaths due to mental and behavioural disorders across Italian regions, though many of these deaths were due to dementia and diseases of the nervous systems that are especially high among old ages (De Vogli, 2013a). In Greece, the prevalence of major depression increased from 3.3% in 2008 to 12.3% in 2013 (Economou, 2016).

A few years after the outbreak of the Great Recession, some commentators talked about “the hoax of suicides due to crisis” and belittled the effects of the economic slump describing temporal trends on suicides as “normal fluctuations” over time. The evidence, however, has now unequivocally shown that there have been indeed additional suicides due to economic problems created by the crisis that cannot be ascribed to normal secular trends. This is now supported three systematic reviews that robustly established that the Great Recession has increased suicides (Oyesanya et al., 2015), mental health problems (Frasquilho et al., 2016), and stress (Mucci, 2016) in Europe and the United States.

Austerity Policies and Health

The decline of GDP per capita in the aftermath of the global financial crisis caused numerous governments to impose austerity policies to reduce budget deficits. While some countries decided to implement stimulus packages, others, especially in the Eurozone, implemented policies of fiscal consolidation imposed by the so-called troika formed by the European Commission, European Central Bank, and International Monetary Fund. In theory, austerity policies of deficit reduction do not need to be regressive and can be achieved by

increasing taxation for the top incomes; in practice, however, they place a disproportionate burden on the lowest incomes as they largely consist of reducing government expenditures by cutting social protection programmes and introducing user fees in healthcare. In Europe, about 80% of fiscal consolidation policies consisted in budget cuts instead of tax increases (Reeves et al., 2013).

When considering the impact of austerity policies on health expenditures from 2010 onwards, notice that indeed there was a relevant budget cut in healthcare in Greece, whose health expenditure (as percentage of GDP) moved from 9.5% in 2010 to 8.5% in 2017. Yet, it remained about at 9% in Italy, and even increased from 16.5% in 2010 to 17.5% in 2017 in the United States and from 8.5% in 2010 to 9.5% in 2017 in the United Kingdom.

Austerity measures produce several direct and indirect effects of physical and mental health (Stuckler et al., 2017). Directly, they can affect access to healthcare services that can result in increased risk for death and diseases. Indirectly, austerity policies may increase unemployment and poverty through the weakening of social protections that buffer health risks especially among low-income populations.

When considering direct effects, some authors have speculated that austerity measures have contributed to the rise in old-age mortality observed in 2014 in high-income countries (Dorling & Stuckler, 2017). A recent study in the United Kingdom found that cuts to social care and financial support for elderly pensioners were related to a rise of mortality among people aged 85 years and over (Loopstra, 2016). The introduction of user fees and cost shifting measures after the crisis increased out-of-pocket expenditures and catastrophic health expenditures among people aged 50 years old and over, according to the Survey of Health, Ageing and Retirement in Europe (SHARE). In Europe, the crisis consisted in an increase of “self-reported unmet medical need” that rose from 0.4% in 2010 to 3.4% in 2012, corresponding to an extra 1.5 million people, especially those affected by chronic diseases and low-income status.

Source: OECD Database (2019). Suicide rates (indicator).

Figure 9. Health spending (total of % of GDP) in United States, United Kingdom, Italy, and Greece, 2000–2017.

In terms of indirect effects, austerity measures may result in reducing public-sector employment causing job losses that can lead to suicides and mental health problems and reducing expenditures or eligibility for unemployment insurance. In the United Kingdom, for example, the Office of National Statistics indicated that there have been 500,000 public-sector job losses between June 2010 and September 2012 (Reeves et al., 2013). Moreover, austerity policies have been found to depress economic growth and prolong recessions. This may, in turn, promote a longer and deeper exposure to joblessness and poverty, especially among socioeconomically vulnerable people and communities.

Life Expectancy Improvements in Times of Recession

While financial crises are associated with rising unemployment, social instability, the rise of suicides and mental health disorders, unmet medical needs, and catastrophic health expenditures, evidence also shows that in the aftermath of the crisis, life expectancy at birth continued to rise in all high-income nations. With the exception of suicide rates, several studies have reported an overall reduction in mortality during times of economic recession (Gerdtham, 2006; Ruhm, 2008a, 2008b; Tapia-Granados, 2005a, 2005b, 2008). A review of economic recessions in Europe between 1970 and 2008 found that, although suicides tended to rise, road traffic fatalities were reduced, producing a slightly favourable net effect on overall mortality (Stuckler, Basu, Suhrcke, Coutts, & McKee, 2009b). Evidence on the improvements of longevity during crises is quite robust, and even in the years following the outbreak of the Great Recession (from 2008 to 2014), longevity showed a continuous upward trend halted by the generalised health reversal in high-income nations in 2015.

While searching for the causes of the decline in longevity around 2015, some authors have wondered whether such mortality crisis can be just a lagged effect of the global financial crisis in 2008. This is uncertain. What seems clearer is that economic crises produce differential impacts on different populations. Although recessions are likely to be detrimental for individuals who lose their jobs, houses, and businesses, and for poor households that experience severe reductions in savings, they may not necessarily cause unhealthy effects in the general population. Little research has analysed the mechanisms by which economic slumps lead to favourable health outcomes, but it seems that crises decrease exposure to dangerous working conditions, overwork, work-related stress, and environmental pollution. Recessions may also increase leisure time and physical activity that, in turn, can lead to activities that enhance health and well-being. Recessions may also have positive effects on social support, a key determinant of health and stress-buffering mechanism, because during recession there is more free time to engage with families and friends and to participate in community and civic activities in society.

Such favourable health outcomes in times of crises are more likely to occur in nations that have strong social protections. Economic buffering mechanisms, such as income subsidies and programmes, reduce stress and can allow people to reintegrate into the workforce after job loss. Targeted government support can also decrease the risk of depression and suicidal ideation (Jääntti, 2000; Vuori, 2002). A cross-national analysis showed that the historical association between unemployment and suicides in Europe varies with the level of investment in unemployment and family support programmes. In countries with low social investment, such as Spain, there was a positive correlation between unemployment and suicide; in countries with high social investments, such as Sweden, however, a rapid increase of unemployment was associated with in suicide reductions over time (Stuckler et al., 2009b).

A similar pattern was observed in Italy, where a study showed that the temporal correlation between unemployment and suicide rates from 2000 to 2010 was negatively associated with per capita expenditure on social services (De Vogli, 2013).

The role of social protection in buffering vulnerable populations from the negative effect of the crisis was highlighted by studies prior to the outbreak of the Great Recession. A study comparing the effects of the 1997 financial crisis in three emerging Asian economies found that, although the crisis increased mortality rates in Thailand and Indonesia, Malaysia—which rejected the IMF and World Bank structural adjustment programmes that required cuts of government spending and austerity—did not experience similar adverse health effects (Hopkins, 2006). An analysis of Eastern European countries showed that those nations that adopted harsher budget cuts after the collapse of the former Soviet Union in 1989 experienced higher tuberculosis incidence rates than countries that did not implement the same policies (Stuckler, King, & Basu, 2008). A study on the 1929 Great Depression in the United States found that American states that introduced greater social welfare spending as a result of the New Deal experienced faster reductions in infant mortality, respiratory diseases, and all-cause mortality (Fishback, 2007).

It may also be plausible to expect that recessions do not necessarily lead to worsening health outcomes in countries committed to progressive taxation or a relatively egalitarian distribution of resources. Notable examples of rising life expectancy in times of economic recession include those experienced by Japan and Finland, for example. In the 1990s, Japan suffered an economic recession that lasted for more than a decade, but experienced faster reduction in chronic diseases mortality than in preceding years of economic growth (Kondo, Subramanian, Kawachi, Takeda, & Yamagata, 2008). In Finland, the collapse of the Soviet Union in 1989 caused the Finnish GDP to drop by a third. Surprisingly, the Finnish all-cause mortality rate also dropped—more sharply during this recession than in the subsequent economic boom. As incomes fell, alcohol consumption declined by more than 10%, and road traffic injuries dropped by one-half (Valkonen et al., 2000). Another case is Cuba, which plunged into its worst economic crisis in history after the collapse of the former Soviet Union; in spite of the sudden deterioration of its economy, the health of the Cuban population actually improved (Franco et al., 2007).

POLICY RECOMMENDATIONS FOR HEALTH PROTECTION IN TIMES OF SOCIOECONOMIC AND POLITICAL CHANGE

This chapter was designed to provide technical assistance for the analysis of population-level mortality crises in times of socioeconomic and political change. It also aimed at discussing future research directions and implications for policy and health promotion in countries affected by economic crises and social instability. The chapter also focused on a few case studies of unexpected mortality crises such as the reductions in life expectancy in advanced economies in 2015, the surprising rise of mortality due to suicides, alcohol abuse, and poisoning among middle-aged White Americans since the early 2000s and the mental health crisis in the United States and Europe in the aftermath of the 2008 global financial crisis. Particular attention has been paid to four countries—the United States, the United

Kingdom, Italy, and Greece—as they represent important case studies for analytical comparison. What have we learned from these case studies?

(1) The analysis of the potential causes of the surprising decline in life expectancy in 2015 among high-income nations raised more questions than answers, for it is still unclear what really caused this unexpected mortality crisis. Hypotheses include the increased mortality in old-age groups in several European countries, including the United Kingdom and Italy, the rise of infant mortality that particularly affected Greece, and the rise of overdose deaths in working-age men that disproportionately influenced the health status of the United States. Paradoxically, it seems almost as if the two countries with the strongest economies and less rapid and lower increase of unemployment, such as the United States and UK, have seen their longevity more affected by the crisis than two countries, such as Italy and Greece, hit hard both by the drastic reduction of GDP per capita and the harsh austerity measures implemented by governments under the pressure of troika. In line with the sharp increase of suicides and mental health problems due to the crisis, Italy and Greece are the two high-income nations that experienced the most rapid decreases of happiness indexes from 2008–2010 to 2015–2017 according to the World Happiness Report, 2018 (Helliwell, Layard, & Sachs, 2018). Italy and Greece also have a quite low happiness index overall, as they occupy the 47th and 79th positions in the ranking, while the United States and United Kingdom occupy the 18th and 19th positions in the Happiness Index. It is still unclear what buffered Greece's and Italy's physical health and why the United States and the UK, which had experienced a small reduction of GDP and applied less harsh austerity measures, are the only two countries that experienced two consecutive years of longevity reduction in 2015 and 2016. Putative mechanisms may include not only stronger welfare policies, but also psychosocial factors such as social cohesion and social relations. Yet, more research is needed to verify such hypotheses.

(2) In spite of differences in terms of possible factors explaining the mortality crisis in different countries, general patterns seem to indicate a need to use a holistic perspective and pay attention to the multiple implications of socioeconomic and political changes that can produce a cascade of effects on health at the individual level. This view is corroborated by considering the crisis of deaths of despair since the adoption of trade liberalisation policies in the United States and the analysis of the health effects of the global financial crisis and austerity policies that have placed a heavy burden on vulnerable populations exposed to job losses, foreclosures, cuts of social protection, increased out-of-pocket health expenditures, and reduced access to healthcare services in both the United States and Europe. There is a need to do more research on the “political economy of health” to assess not only proximal determinants of mortality at the individual level, but also “the causes of the causes” of health by integrating different levels, pathways, and mechanisms of influence between policy change and health outcomes.

(3) The mortality crises that followed policy and socioeconomic change affected different social classes differently. Affected populations include those who lost their job after trade liberalisation policies in the manufacturing sector, or those who lost their businesses after the recessions of the global financial downturn, or those who could no longer afford to pay for healthcare services after the adoption of austerity policies to reduce budget deficits caused by the crisis. Evidence shows that unless governments intervene boldly to protect the most vulnerable populations from its effects, financial crises can have detrimental effects of health. Yet, not all people have been hurt by the crisis. Counterintuitively, however, life

expectancy continued to rise in the aftermath of the global financial downturn, corroborating previous evidence showing that recessions, especially for countries that have stronger welfare services and lower inequality, can even result in a “healthy degrowth.” Although recessions can kill some of the populations affected by its economic changes, they may not necessarily cause unhealthy effects for the general population. Economic slumps may lead to favourable health outcomes such as decreased exposure to dangerous working conditions, overwork, work-related stress, and environmental pollution. Recessions may also increase leisure time and physical activity, and free time for social relations and social engagement that, in turn, can lead to activities that enhance health and well-being.

(4) In spite of country-specificity and contextual factors, there may be a few lessons to be learned about common determinants and shared patterns of explanations for these mortality crises. On the basis of existing scientific literature and ad hoc descriptive data analyses, it would be useful to develop coherent conceptual frameworks that focus on a variety of possible mechanisms connecting political and economic changes and unexpected increases in mortality. Psychosocial factors must be given particular attention for modern mortality crises are increasingly affected by mental health problems and psychological and social issues. In times of crises, it is essential to develop interventions that promote psychological resilience and restore hope and sense of purpose in a population affected by the loss of identity and meaninglessness of adverse socioeconomic and political change. Individual-level and structural-level programmes can complement one another and work effectively in saving lives and promote health in times of crisis.

(5) Large and sudden socioeconomic changes following policies such as a trade liberalisation and austerity, even when they are truly necessary and important for economic benefits, can entail not only enormous social and health problems but also political turmoil. Social costs of underserved communities on the receiving end of trade liberalisation and deregulation policies are generally underestimated or neglected by governments, mainly driven by the need to promote GDP growth and meet the interests of the most influential sectors of society including banks and large corporations. Yet, profound social changes, such as those observed on occasion of recent political or economic reforms, may have unexpected long-standing effects on society and exacerbate social conflicts, anger, government distrust, and the rise of populist and extreme right-wing parties such as those who have gained support in the United States and Europe since 2008. Evidence on the association between the area-level prevalence of deaths of despair and support for Trump in 2016 US election is revealing (Monnat, 2016). The analysis of past and current cases of social examples of political change following socioeconomic crises and austerity programmes, such as the rising support to the Nazi party after the introduction of fiscal consolidation measures in Germany between 1929 and 1933 (Galofre-Vila et al., 2017), may be crucial in informing policy leaders how to prevent future political crises.

(6) The rise of overdose deaths after the implementation of trade liberalisation policies in the United States in the early 2000s caught most epidemiologists by surprise. Usually, addictions are conceptualised and treated as psychological problems, and interventions are performed at the individual level. Some authors have reduced the case of the so-called deaths of despair to a mere increased availability of drugs and have thus called for interventions to reduce the supply side of opiates. Of course, clinical interventions and policies to restrict availability of drugs are important. Yet, the root causes of the rise of mortality due to drug overdose deaths need to be found in the social, economic, and political factors that caused

massive job losses in the manufacturing sector. Individual-level interventions to deal with mental health disorders caused by an economic problem are not very effective, because they do not tackle the upstream factors influencing mental health in the first place. Reducing availability of drugs may be useful. However, if people take drugs out of despair or sense of meaninglessness and powerlessness, even if you remove all drugs from the market, the desperation remains. Mentally affected people will find other way to express their psychological suffering. Economists and politicians designing policy changes such as trade liberalisation measures should be expected to deliver a health and mental health impact assessment to make sure that the economic benefits of a free trade agreement do not come at high social and psychological costs.

(7) Austerity policies are a failed, unhealthy experiment on countries and populations. They have not only harmed the most vulnerable sectors of society, but also failed to restore economic growth, especially in the Eurozone. Austerity policies have been revealed to be self-defeating not only because they further increased inequities in wealth and health, but also because they exacerbated the debt crisis they were supposed to overcome. Countries that have applied harsher budget cuts experienced sharper declines of GDP per capita and rises of unemployment rates. In a recent empirical analysis, even the IMF, which championed austerity and structural adjustment programmes in the developing world for over three decades, admitted that “fiscal consolidation has contractionary effects on private domestic demand and GDP” (Guajardo, Leigh, & Pescatori, 2011). Clearly, countries with a high debt-over-GDP ratio, such as Portugal, Ireland, Italy, Greece, and Spain, must find revenues to contain the deficit. Yet, rather than operating regressive cuts on social welfare and healthcare, they can resort to progressive taxation and targeted social benefits. It is time to make the rich and multinational corporations pay their fair share of taxation. Top marginal tax rates are at the lowest level since the end of World War II in most high-income nations, and a large proportion of world’s wealth is hidden in tax havens. This, for example, allowed about 60 multinational corporations, including Amazon, Netflix, IBM, and General Motors, to pay 0% in taxes in 2018!

(8) Action to reduce inequality and limit or abolish tax havens is urgent. The lost tax revenue from money transferred offshore is partly responsible for the high levels of debts, and it is forcing governments to resort to austerity and budget cuts on healthcare, social services, and education. A report entitled *The Price of Offshore Revisited* from the Tax Justice Network (2012) estimated that the global super-rich have between \$21 and \$32 trillion hidden in tax havens. The report estimated that this amount of unreported wealth would have generated income tax revenues of between \$190 and \$280 billion a year. Recently, a group of progressive Europeans led by the economist and author Thomas Piketty has drawn up a bold new blueprint for a fairer Europe, in response to the increasing inequality in high-income nations. The plan, crafted by more than 50 economists, historians, and former politicians from half a dozen countries, includes huge levies on multinationals, millionaires, and carbon emissions to generate funds to tackle the most urgent issues of the day, including poverty, migration, climate change, and the EU’s so-called democratic deficit. There is strong evidence that a more equitable society is a happier, healthier, and more economically successful society. The IMF indicates that an optimal level Gini coefficient to perform well in terms of poverty reduction and economic growth is about 27, or the level of inequality of Northern European countries (Grigoli & Robles, 2017). IMF economists have also recognised that more equity can be a protective factor against future financial crises. As they wrote,

“redistribution policies that prevent excessive household indebtedness and reduce crisis-risk ex-ante can be more desirable from a macroeconomic stabilisation point of view than ex-post policies such as bailouts or debt restructurings” (Kumhof, 2011).

(9) The crisis represented a unique opportunity to tackle the root causes of the global financial crisis such as financialisation, deregulation, and indiscriminate capital mobility and reevaluate some of the policies and principles that increased inequality and guided economic development since the late 1970s. As the IMF admits in a surprising report entitled “Neoliberalism: Oversold?” (Ostri, Loungani, & Furceri, 2016), the current model of economic development is increasing inequality, which in turn generates social, economic, and environmental crises. It is time to evaluate the feasibility of a new system that promotes equity, well-being, and sustainable development. However, policy responses following the beginning of the Great Recession were regressive and inadequate. They consisted in expensive bailouts for the “too-big-to-fail banks” exposed to toxic mortgage debts that had accumulated from reckless investments during the years of financial speculation and large operations of quantitative easing. IMF economists estimated that, worldwide, the bailouts cost taxpayers a staggering \$11.9 trillion, about a fifth of the entire globe’s annual economic output. This made the banks that caused the 2008 financial collapse even more powerful. They are now larger, still unregulated, full of toxic assets, and capable of neutralising governments’ attempts to introduce more stringent financial regulations. A second major policy response after the crisis was a massive operation of quantitative easing that consisted in an impressive 21 trillion dollars globally (Global Central Bank Balance Sheet Assets, 2018). This vast amount of financial resources, however, hardly trickled down to the real (nonfinancial) economy, small businesses, households, and people affected by the crisis. In the United Kingdom, the Bank of England created a quantitative easing (QE) programme of £375 billion, corresponding to about £6,000 for every person. However, it has been estimated that for every £1 created under QE only 8p trickled down to the real economy (Al-Daini, 2015), with the rest getting trapped in financial markets, boosting the value of bonds and stock markets that are disproportionately owned by the top socioeconomic classes in society. Ironically, both John Maynard Keynes and Milton Friedman were in favour of quantitative easing aimed at the real economy. Some alternative ways to stimulate the economy are needed. Some have proposed that a most effective way to boost the economy would be for central banks to create money and grant it directly to governments or public institutions and allow governments to spend it directly into the real economy (New Economics Foundation, 2013). These types of proposals include “People’s Quantitative Easing,” “Sovereign Money Creation,” and “The Helicopter Money.”

(10) National and international institutions have missed not only the opportunity to move away from the neoliberal economic paradigm that led to the 2008 global financial downturn, but they have also failed to legislate new reforms necessary to prevent another financial downturn from occurring in the future and avoid the side effects of trade liberalisation policies. John Maynard Keynes showed lucidly that although unfettered free markets have a built-in predisposition to crash at intervals, it is possible to reduce the risk of financial instability through government interventions, as demonstrated by the very low number of banking crises during the postwar era of New Deal-style policies and the Bretton Woods System. Yet, in spite of some financial reforms such as the Dodd-Frank Act in the United States, little action has been taken to reduce systemic risk internationally. A new system of financial regulation at the global level is necessary. Some have proposed a new Bretton Wood

System of capital controls, bank regulations, and containment of financial speculation. A set of comprehensive and stringent regulations of global finance and taxes on international financial transactions has been advanced by numerous writers including John Eatwell and Lance Taylor, authors of *Global Finance at Risk: The Case for International Regulation*. They proposed a new economic architecture regulated by a new “World Financial Authority,” specifically designed to manage the threat of systemic risk and financial contagion. In the same vein, a 2009 report from the United Nations Conference on Trade and Development (UNCTAD), entitled “The Global Economic Crisis: Systemic Failures and Multilateral Remedies,” called for a new system of global financial regulations to curb the indiscriminate speculation and financial risk taking that caused the 2008 Great Recession.

Chapter 288

THE MORTALITY CRISIS OF THE FORMER SOVIET BLOC COUNTRIES, 1989-2014

*Giovanni Andrea Cornia**

University of Florence, Italy

INTRODUCTION

The transition to the market economy and liberal democracy of the former communist countries of Europe represents the most vivid example of how potentially favourable economic and political reforms may lead to massive mortality crises. The transition of these countries was universally greeted as a key step towards world peace and economic progress. The months preceding the beginning of this historic watershed were characterised by widespread hopes for improvements in political freedoms, economic growth, living standards, and life expectancy which, during the prior 20 years had improved more slowly than in capitalist OECD countries, or had deteriorated. Despite these hopes, the years after 1989 were characterised by a severe transformational recession, a fall in output and incomes, the rapid impoverishment of large sections of the population, rising income and assets concentration, widespread social dislocations and an acute mortality crisis.¹

Despite its magnitude and a growing number of studies, the transition mortality crisis has attracted limited political attention by national authorities and international agencies. When it was acknowledged, it was attributed to past shocks or irrelevant factors, retarding in this way the introduction of appropriate policy responses. In a way, the recent European mortality crisis is a telling example of how potentially favourable reforms may lead to large health and social costs.

¹ Over 1989 and 1996 alone, the number of poor and unemployed in the region rose respectively by 100 million and 10 million while the crime rate tripled (UNICEF, 2000).

MORTALITY AND LIFE EXPECTANCY TRENDS

With the exception of Slovenia, during the first reform years, male life expectancy at birth fell and the Crude Death Rate rose in all European economies in transition. For instance, over 1990–91, Poland recorded about 30,000 excess deaths in relation to 1989, while Hungary registered about 7,000 excess deaths over 1992–93 (Table 1 and Annex Table 1). Thus, in Central Europe too, the loss of human life was sizeable from a welfare perspective, though not in terms of demographic trends. In this sub-region, the economy, living standards, and life expectancy at birth (LEB) already started to recover in 1992–94 while mortality rates and the number of deaths declined. As a result, over 1989–2014, the five Central European countries taken together recorded about 730,000 fewer deaths than would have been the case had the 1989 number of yearly deaths remained constant throughout this period (Table 1 and Annex Table 1). While country-specific factors played a role, the steady fall in death rates in these countries after 1991–92 appears to have also been due to some common factors. All of them began the transition with much smaller economic and social distortions than the CIS countries, they all experienced less acute and short-lived recessions and inflationary spikes, and only moderate surges in income and asset inequality.² All of them introduced extensive labour market programmes to soak up transitional unemployment, while public expenditure on health increased, and alcohol consumption either stagnated or increased modestly. Family instability and distress migration during this period were also modest. Moreover, none of these countries experienced the massive weakening of state institutions in the area of law-and-order and personal security that was observed in several CIS countries. Finally, their faster political democratisation and the active role played by intermediate social bodies (such as cooperatives, churches, trade unions, cultural and sports associations, and so on) contributed to keeping up the pressure on incumbent governments to tackle the social dislocations inevitably entailed by the transition.

The mortality crisis was much sharper in South Eastern Europe, the Baltic States, and especially the members of the former Soviet Union mainly inhabited by Slavic populations, that is Belarus, Kazakhstan, Moldova, the Russian Federation (henceforth Russia), Ukraine, and Lithuania. In these countries, the initial recovery in economic activity and male LEB recorded over 1995–98 was interrupted in 1998–2003 by the 1998 Rouble crisis and subsequent devaluation, default on the public debt, and capital flight, and a sluggish economic performance over 2000–2002 that were quickly transmitted to neighbouring countries. LEB started recovering steadily in 2003 in Russia and in 2005 in Belarus and Ukraine. In Russia, male LEB rose by 6.7 years between 2003 and 2014, suggesting that the country had exited

² Popov (2000) and Cornia and Popov (2001) developed a cumulative measure of ‘initial distortions’ as a percentage of GDP for all economies in transition. This measure is the sum of defence spending exceeding 3% of GDP (a level regarded as normal), deviations from a normal level of the industrial structure (particularly the over-representation of the inefficient heavy industry) and heavily distorted trade among the former Soviet republics and lightly distorted trade within the other socialist countries. While Hungary and Slovenia had an index of initial distortions equal to around 4% of GDP, in the Baltics the index ranged between 67 and 71 and in Russia it reached 41. Regression analysis showed that this measure of initial distortions retarded growth in a statistically significant way. Other initial distortions included very different degrees of money overhang, i.e., the excess amount of cash in circulation as a share of GDP that, with a rapid price liberalisation, caused very different rises in the rate of inflation and macro instability, from moderate in the Czech Republic to hyperinflation in Russia. This problem, and the inability to develop rapidly a new tax system contributed to the Ruble crisis, and to the default on the public debt of 1998–99, which were years when LEB fell again.

the mortality crisis of the prior 15 years. Yet the 1989 level of male LEB was only reached again in 2012. In Belarus and Ukraine, the 1989 level of male LEB was reached again in 2013 (Table 1).

What were the factors behind this rebound? Grigoriev et al. (2014) show that the main causes of death that triggered the increase in mortality over 1989–94 (that is, cardiovascular and external causes) were the same that explained its decline over 2004–10 and beyond (see later). The possible explanations put forward to explain such an important rebound in Russia include a declining consumption per capita of spirits, accompanied by an increase in wine and beer drinking. It also includes a decline in alcohol poisoning; diet improvement (but no changes in smoking); a rise in health expenditure per capita from \$PPP 300 in 1995 to \$PPP 998 in 2010; an increase in cardiac surgeries per 100,000 people of over 35 years of age from 21.7 in 1995 to 97.5 in 2010. The sources of social stress also became less threatening, with a return to a more stable life. With the recovery of the Russian economy over 2003–10, there was a fall in the unemployment rate from 9.8% to 7.5%, a drop in the poverty rate from 29% to 12.6% and a modest fall in the crime rate. Similar gains were recorded in Belarus and the Baltic countries, while in Poland, Czech Republic, and other Central European countries these kind of improvements had occurred just after the initial crisis of 1989–1992. In turn, the marriage rate recovered after the 1999–2005 while the total divorce rate declined, starting in 1993 in Ukraine, in 2000 in Estonia, and in 2002 in Belarus and other countries (Transmonee, 2017). Income inequality seems also to have stabilised since the early 2000s, although in the CIS countries the available data are not very reliable because of the under-reporting of top incomes.

While these trends are a source of hope, it is equally true that except for the Central European countries besides Hungary, male LEB in the region only returned to its 1989 level in the early 2000s or over 2011–2013 (Table 2). This has entailed a large loss of male life expectancy that continued in some cases until 2011–2013. The trend in female LEB is similar if more attenuated (Table 3).

How large was the human cost of the transition? Calculating the number of ‘excess deaths’ during the transition requires the availability of the Standardised Death Rate (SDR) for each of the 21 countries in Table 1 and the years 1989 to 2014 – using 1989 as the base year for which the age structure of the population is assumed to remain constant over 1989–2014. This would enable a separation of the increase in the number of deaths due to higher age-specific mortality rates from those due to population ageing. However, at the moment, the SDR for all these countries and years is not available to this author. To give the reader an idea of the impact of ageing on the total number of deaths, the last four columns of Table 1 list the changes over 1989–2014 in the age dependency ratio (65+/15-24). These data indicate that with the exception of Slovenia, the Baltics, Romania, and Bulgaria, population ageing seem to have been a moderate entity in most regions, especially in the Slavic and Central Asian countries. This seems to suggest that, at least in these countries, a good part of the ‘transition mortality crisis’ was due to an increase in age-specific death rates, rather than to population ageing. In any case, the last four columns of Table 1 give an initial idea of the bias introduced by the use of the CDR instead of the SDR. Except for the countries marked in yellow, this bias seems limited.

Source: own compilation based on Transmonex (2017).

Overall, the European transition crisis caused some 18 million cumulative excess deaths over 1989–2014, of which a rough estimate (taking into account the 1989–2014 changes in the age dependency ratio 65+/15-64) suggests that at least 80% were due to a rise in age-specific death rates. The most shocking increase in excess mortality was observed in the Slavic countries of Russia, Ukraine, and Belarus (Table 1). At the same time, the Central European countries recorded 746,000 fewer deaths due a steady decline in the number of yearly deaths. Analysis of the mortality dynamics over 1989–2014 shows that because of the sharp fall of LEB over 1993–94 and again over 1999–2005, the number of yearly excess deaths in relation to 1989 in Russia exceeded 700,000 units (Table 1 and Annex Table 1). While over 2002–05, part of this excess mortality was due to population ageing (ibid), the second dip in health conditions of 1999–2005 generated 3.2 million excess deaths, as opposed to roughly 1.6 million over 1989–1994. Overall, over 1989–2014 in Russia, the sum of yearly excess deaths in relation to the 1989 level reached a staggering level of 12.2 million (Table

1). Also in this case, a modest part of this figure is explained by a (limited) ageing of the population, especially over 1989–2000 (last three columns of Table 1). Indeed, much of the excess mortality in these countries was due to a rapid rise in death rates for the male 15-59 age group, which peaked in the mid-to-late 1990s and again over 1998–2003/04 (TransMonEE, 2017).

Large increases in the number of deaths relative to 1989 and the population of that year were also observed in Ukraine and Belarus. In the latter country, male LEB fell for 11 years in a row from 1989, stagnated for another five years, then only returned to its 1989 level in 2012–13. In Estonia and Latvia, male LEB returned to its 1989 level in 2002 and in Lithuania in 2009 (Table 2). The crisis was also acute and long lasting in the countries of Southeast Europe.

Notes: *1989-90; **1991-1999; *** refers to 1991. n.a. means 'not applicable' as the country recorded improvements throughout the transition; n.d. means not available. Two central Asian countries and all countries of the former Yugoslavia except Slovenia were dropped because of missing data, lack of comparability, border changes and war.

Notes: * 1989-95. ** 1991-92. indicates that the maximum loss was realised over the first two reform years.

n.a. means that the country recorded steady improvements throughout the transition.

To put things into perspective, it must be noted that by 1994, the LEB of Russian males had already fallen to 57.6 years, that is, 6.6 years less than in 1989 and three years less than that of India, which was then a poor agrarian economy. Likewise, over 1998–2003, male LEB fell by 2.7 years. This crisis was unprecedented in the 20th century for countries at peace and unaffected by famines or major epidemics. To underscore the dramatic nature of these figures, it suffices to mention that World War Two caused 3.3–4.6 million civilian casualties in Poland and 7 million in the USSR (Alderson, 1981). Likewise, the 1929–33 famine caused by the collectivisation of the Kulaks' land in Russia, Ukraine, and Belarus caused an estimated additional 9 million deaths.

The transition mortality crisis resulted from the overlay of a long-term pre-1989 stagnation in health conditions (not the focus of this chapter) and of an acute adjustment crisis. As a result, the mortality gap with the Western European countries and between Russia and its former satellites rose sharply. For instance, the male LEB gap between Poland and

Russia rose from 4.5 to 8.5 years over 1989–2014 and that for female LEB from 1.0 to 5.1 years (Tables 2 and 3). In turn, the male and female LEB gap in relation to Italy respectively rose from 6.9 to 14.7 years and from 5.1 to 8.2 years. It is thus important to understand why in an era of growing opportunities associated with the market economy, the health status of many CIS countries fell further behind those of their former satellites of Central Europe and of Western Europe. The rapid reduction in cardiovascular mortality that began in Russia during the last decade, however, has started closing this health gap.

IMMEDIATE CAUSES OF DEATH

What were the disease-specific causes of the fall of LEB during the transition? Overall, the surge in death rates resulted from diverging trends for different groups of diseases.

Diseases Exhibiting a Stable or Declining Trend in Death Rates

Mortality due to respiratory ailments mainly followed a declining trend, possibly because of the fall in the emission of pollutants into the atmosphere due to the sharp industrial recession experienced during the initial years. From the mid-1990s, the trend became less stable, but in no country did it lead to a sizeable rise in deaths. Also of limited importance were the increases in cancer mortality, which showed a stable, slow, upward trend that played a greater role in countries with smaller shifts in overall mortality.

Diseases Showing a Fast Increase in Death Rates

Close to 40% of the increase in standardised male mortality and a smaller but non-negligible share of female mortality was caused by an epidemic of heart diseases, such as ischaemic heart diseases, sudden deaths due to circulatory problems, and strokes. Interestingly, the fall in deaths due to these diseases and to external causes accounted for most of the decline in mortality recorded in the Central European countries after 1991, and in the Baltic States after 1995–96. In Russia, mortality due to these causes started dropping from the mid-2000s due to the ‘preventative cardiovascular revolution’ that took place following a rise in the implantation of stents and bypasses (Grigoriev et al., 2014). Indeed, the number of cardiac interventions per 100,000 people of over 35 years of age quadrupled between 2000 and 2010 (ibid). In the countries of the former Soviet Union, the external causes of death (poisoning, suicide, homicide, and all sorts of accidents) also explain an important share of the overall increase in mortality among young people, especially men. For instance, in the Russian Federation the murder rate among 35–39 year-old males increased by 223% between 1989 and 1993 alone (UNICEF, 1994). The transition was also characterised by an increase in deaths due to motor, train, and plane accidents, alcohol and other types of poisoning, accidental drowning, fires, and work accidents, that is, deaths related to the weakening of the state’s regulatory capacity and the erosion of safety at work.

The escalation in mortality was also in part explained by an upswing in deaths due to cerebrovascular and digestive diseases, including stress-related diseases such as ulcers and cirrhosis of the liver. Finally, there was also a sharp percentage increase from very low levels in mortality due to diseases of poverty (that is, infectious, nutritionally-related, parasitic, and sexually transmitted diseases) such as diphtheria, tuberculosis, and – later on – HIV-AIDS. While very pronounced in relative terms, this rise was almost negligible in absolute terms and was possibly related to the emergence of an underclass of ‘marginal’ people (vagrants, intravenous drug users, and commercial sex workers) unreached by the public health system. Yet because this rise took place from a very low level, it explains little of the aggregate mortality rise.

POPULATION GROUPS AFFECTED

A priori, one might have plausibly surmised that the health dislocations caused by the transition would have most affected the biologically more vulnerable groups: children, pregnant women, the elderly, and the disabled. In reality, the mortality crisis affected other social groups.

Gender

In most countries and for all age groups, men were far more affected than women. Indeed, where death rates soared, the transition exacerbated an already high gender gap. In Russia, for instance, the female-male LEB gap rose between 1989 and 2014 from 10.3 to 11.2 years (Transmonee, 2017). In contrast, in countries where death rates fell, the gender mortality gap narrowed: in the Czech Republic, the female-male LEB gap dropped over 1989–2014 from 7.3 to 5.9 years (*ibid*). The production of specific hormones, testosterone in particular, seems to provide women with greater protection against stress-related mortality. In addition, women generally depend on a more diversified portfolio of activities and social relations. Such diversification shelters them from the anxiety and dejection experienced by men during periods of rising unemployment, loss of social status, inability to provide for one’s own dependents, and deteriorating family life.

Age Groups

The fastest relative upswing in mortality rates over 1989–1994 and 1998–2005, and its drop since 2005, was recorded for 20-39 year-olds (who were affected mostly by a sharp rise in external causes of death), while the most rapid absolute increase was observed for 40-59 year olds (who were mainly hit by a rise in cardiovascular deaths). For people above 60 years of age, and even more so for those above 70, there was only a small increase or even a decline in mortality (Cornia and Panicià, 2000). Likewise, infant and child mortality rates declined everywhere (Transmonee, 2017).

Level of Education

Previous studies have documented the steep mortality gap existing among people with different levels of education. Higher education allows individuals to acquire and process new types of information more easily than people with 'low' education, an essential advantage during periods of rapid transformation. Higher education also favours greater employment mobility, better management of limited financial resources, and a prudent screening of the risks connected with smoking, taking drugs, and excessive drinking. *Ceteris paribus*, a rise in overall mortality was therefore expected to disproportionately affect people with low education. But the reality has been grimmer than such predictions. Indeed, mortality differentials by level of education widened during the transition. Shkolnikov et al. (1998), for instance, showed that in Russia, the temporary life expectancy gap between the best and least educated men and women in the 20-69 age group rose from 1.63 and 1.44 in 1988-89 to 1.89 and 1.75 in 1993-94. And Shkolnikov et al. (2006) show that the life expectancy differentials at age 40 between people with high and low education hardly changed over 1988 and 1998 in the Czech Republic, while rising in Russia and Estonia from 5.14 to 10.21 years and from 3.30 to 8.97 years.

Marital Status

The rise in death rates disproportionately hit a growing number of people living alone. A drop in the marriage rate and – in the Slavic countries of the former Soviet Union – a rise in the divorce rate, raised the number of adults living alone. This phenomenon was exacerbated by the surge in the number of widows and widowers due to the initial (1989-95) and subsequent (1998-2003) surge in adult male mortality, and to a lesser extent female mortality, that raised the number of widows and widowers.

Migrant Populations and Place of Residence

Migrants, especially distress migrants, normally face a higher risk of mortality than people who remain in their communities. The impact on aggregate mortality of this phenomenon rose in intensity, as domestic and international migration skyrocketed in the region following the breakdown of states, the return of troops posted abroad, the inflow of refugees fleeing ethnic strife, industrial restructuring, and unemployment.

In most of the region, mortality rates have historically been higher in rural than urban areas. Since 1990-92, however, this tendency started to be reversed, because of the greater unemployment, stress, and crime levels of cities, particularly in mono-industrial cities affected by the collapse of dominant state factories (Milanovic, 1996). Urban mortality also increased because of a surge in the number of deaths among vagrant rural residents who moved to towns after the abolition of residence permits and the liberalisation of internal migration. In Russia, for instance, the rural-urban LEB difference decreased from 2.4 to 0.8 years between 1992 and 1994 due to a faster rise in urban mortality rates linked to violent causes and cardiovascular problems (Shkolnikov and Cornia, 2000).

Ethnic Origin and Employment Status

Mortality appears to have risen more rapidly among certain ethnic groups. For instance, Krumins and Usackis (2000) showed that before the transition, the standardised death rate in Latvia was 10% higher among ethnic Russian males than among ethnic Latvians. This differential rose to 17% by the mid-1990s. Similarly, in the Czech Republic, Dzúrová (1996) found a high correlation among cross-district mortality, ethnic heterogeneity, and the proportion of the population of Romany origin. Jozan (1997) reported similar results for Romania and Hungary. It is unclear, however, whether these differentials would still be valid after controlling for levels of education and skills, unemployment, and so on. Finally, Shkolnikov and Cerviakov (2000) found that in Udmurtia (Russia), the mortality among 20-59 year-old males was higher among the Udmurt population than among people of Slavic and Tatar origins, but were unable to conclude whether this depended on genetic or socio-economic factors. Finally, mortality grew faster among the unemployed, people with part-time jobs, handicapped pensioners, and people affected by fast labour turnover. This point is discussed further in the next section.

In conclusion, the evidence suggests that the transitional mortality crisis mainly affected an underclass of young and middle-aged men and – to a lesser degree – women with low-level education and skills and unfavourable labour market conditions. These people often lived in poverty (which affected their psychological status and alcohol consumption), inhabited in or migrated to urban areas, lived alone, had been detained in the past by the police for more than three days, and were of migrant or ethnic-minority backgrounds. The retrospective case-control study conducted in 1999 on 500 men of 20-55 years of age in the Udmurt republic of Russia confirms that the victims of the transition had this kind of social profile (Shkolnikov and Chervyakov, 2000; Shkolnikov et al., 2004).

UNDERLYING CAUSES OF THE MORTALITY INCREASE³

Several hypotheses have been put forward to explain the increase in transitional mortality. Some have shown their limited relevance and are no longer the object of discussion. They are briefly mentioned hereafter for completeness. Others emphasised factors that do not require a policy response, either because the problem does not exist anymore, or because it stems from past problems, the influence of which can no longer be offset.

Explanations of No or Limited Relevance

Glasnost in Statistics

According to this explanation, a large part of the mortality rise was due to changes in statistical conventions and greater transparency. It is well known that the former communist

³ Schiering et al. (2018) reviewed 39 cross-national, multi-variable, peer-reviewed studies on the causes of the transition mortality crisis in Eastern Europe and the former Soviet Union. They found that inequality, unemployment, social subsidies, a lack of democracy, poor economic performance, and religious composition were the leading factors explaining the observed mortality outcomes. At the same time, the reviewed studies failed to establish a connection between mortality and diet, drinking patterns, liberalisation, trust, health expenditure, and war. Such results coincide to a great extent with those reported below.

authorities deliberately misclassified the number of deaths due to alcoholism and violent causes. Yet the removal of this distortion barely affected the global mortality picture. Second, the pattern of mortality changes observed in the 1990s throughout the region was uniform, a fact it is hard to attribute to coordinated data falsification by many independent statistical agencies. Third, detailed investigations of death statistics indicate that for several decades, their quality and coverage were – with few exceptions – of standards similar to those of Western countries (Anderson and Silver, 1990). The new mortality data could also have been affected by changes in statistical conventions, disease classifications, and geographical boundaries. However, an examination of the data showed that these changes explained only small variations in mortality for narrow subpopulations.

Ecocide

According to this argument, the mortality crisis was largely due to the current and lagged impact of past environmental neglect. During the socialist era, acute environmental problems led to a high incidence of deaths due to bronchitis, pneumonia, influenza, neoplasms, and genetic disorders. Yet ecocide cannot explain the transitional mortality crisis because during the initial phase of the reforms, emissions of harmful substances declined sharply in line with a contraction of industrial production and the adoption of more efficient and less polluting technologies. In Russia, for instance, the emission of harmful substances into the air dropped from 34 million tons in 1990 to 21 million tons in 1995–96 (Goskomstat, various years). The irrelevance of this explanation is confirmed by the steady decline of mortality due to respiratory diseases.

Cohort Effects

The mortality crisis in Russia and Ukraine also cannot be explained by the delayed consequences of the debilitation experienced by people born during the 1929–34 famine and World War Two. Indeed, an analysis of cohort mortality in Ukraine over 1965–94 concluded that the male war birth cohort experienced higher mortality in the 1990s than the adjacent cohorts, but also that this was not enough to explain the overall increase in mortality after 1989 (Godek, 1997). A similar analysis for Russia (Blum, Avdeev, and Zakharov, 1997) shows that in the 1990s, the three-year cohort born during the difficult years of 1942–44 experienced an increase of 16% in the risk of dying in relation to the adjacent cohorts. Similarly, the cohorts born between 1933 and 1934 experienced a 9% higher risk of dying in relation to the cohorts born in 1931–32. However, the share of deaths explained by this ‘debilitation hypothesis’ is not too important, as the overall increase in death rates over 1991–94 among males aged 40–50 and 50–60 years exceeded 75%. Second, the percentage increase in death rates during the transition was much higher among 20–40 year-olds, that is, cohorts born during a period of relative prosperity. Also, women born during World War Two and 1929–33 should have also suffered higher risks of death later in life, a fact only partially borne out by the data for the 1990s. Fourth, during the transition, the rise in mortality also affected areas of the former Soviet Union that had not been hit by the demographic catastrophes of the 20th century. Likewise, in Poland the mortality rates of cohorts born during World War Two fell more quickly than those of the preceding cohorts. Finally, the ‘postponed death hypothesis’ (which suggests that the liberalisation of alcohol sales of 1989 led to an increase in consumption that proved lethal for socially weak groups whose life was saved by Gorbachev’s anti-alcohol campaign) does not stand up to scrutiny. A comparison of

LEB gains during the anti-alcohol campaign, with its rises over 1989–1994 suggests that this hypothesis may explain only a modest part of the surge in deaths over 1989–94 and none of the 2.6-year decline in male LEB that took place over 1998–2003 in the aftermath of the Ruble crisis and devaluation.

Recession, Impoverishment, and Malnutrition

To be sure, the belt-tightening imposed by the transitional recession entailed a sizeable drop in food expenditure. Yet in view of the high food intake prevailing in the region before the transition and of the considerable scope for substituting cheap sources of nutrients for expensive ones, even large drops in consumption expenditures did not seriously exacerbate the risk of death due to undernutrition (Cornia, 1994). The increase in deaths due to infectious and nutrition-related diseases among male adults was caused by reduced access to shelter, poor hygiene, and inadequate healthcare among a class of ‘marginals,’ vagrants, and homeless people. Thus, impoverishment and malnutrition may have been relevant only in very few poor and isolated parts of Romania, Russia, and Ukraine. Adamets (1997) reports that in Ukraine, only 25 deaths due to starvation were recorded in 1995 out of a total of almost 800,000 deaths that year.

Unhealthy Lifestyles (Poor Diet, Smoking, and Drinking)

This explanation focuses on causes of death and population groups similar to those observed during the transitional crisis. However, accepting this explanation entails that mortality should have risen slowly and should have done so after an extended exposure to risky behaviours. In addition, the risk factors mentioned above should have worsened, a fact not always borne out by the evidence. Furthermore, changes in relative prices and improvements in trading raised the consumption of vitamins and minerals from fruits and vegetables. Similarly, a rise in the relative prices of meat, milk, and dairy products reduced the intake of saturated fats, thus lowering the risk of cholesterol-induced mortality. Mielecka-Kubien and Zatonski (1997) claim that the drop in cardiovascular mortality among Polish men after 1992 was largely driven by respective falls of 25% and 60% in the consumption of animal fat and butter. Likewise, over 1989–95, tobacco consumption appears to have slightly declined or stabilised at a high level throughout the region, as incomes dropped, the prices of imported cigarettes soared, and educational efforts started producing an effect. In any case, as noted, death rates due to lung and other types of cancer rose along a slow stable trend and seem to be little related to recent changes in smoking prevalence. They cannot explain the rapid surge in circulatory and violent deaths.

Relevant but Incomplete Explanations

Weakening Healthcare Systems

Since the onset of the transition, most Central European countries increased public health expenditure per capita and made greater use of modern drugs such as beta-blockers, which reduced the incidence of cardiovascular deaths. For instance, in the Czech Republic, the decline in cardiovascular mortality among middle-aged and old-aged people coincided with a surge in public health expenditure from 5% to 7.4% of GDP between 1990 and 2004

(Rychtarikova, 2004). These higher allocations fostered an increase in the number of heart interventions and improved the overall quality of public health. In contrast, countries such as Russia, Ukraine, Latvia, and Lithuania experienced a fall in health expenditures per capita of between 15 and 30% during the initial phase of the transition and stagnation since then. This gap has partly been reduced over time, and World Bank-WDI data for 2015 show that the Public Health Expenditure/GDP ratio ranged between 4.5% and 6% in Central Europe versus 2.9% in Ukraine and 3.4% in Russia.

In Russia and other CIS countries, the rise in the number of deaths for curable diseases among hospitalised patients and the temporary breakdown of vaccination systems in the early 1990s (Shkolnikov and Cornia, 2000) suggests that cuts in public expenditure played a role in the early years of the crisis. According to some estimates, one-fifth to one-quarter of the LEB gap between Russia and Western Europe could be attributed to deaths from amenable diseases.

Yet the reduced access to and declining quality of health services and their subsequent slower increase in quality cannot explain why mortality rose faster among men than women and why it surged only for a few diseases but not for others such as cancer, respiratory diseases, and neonatal and perinatal problems. Finally, it cannot explain the jump in the number of non-amenable causes of death such as strokes and violent deaths, that is, deaths that accounted for an important share of the total increase in mortality. Indeed, the relation between health spending per capita (and indirectly health spending/GDP) and LEB is concave.

While an initial growth in health spending per capita generates a rapid increase in LEB, beyond a threshold of around 2,000 international 2010 dollars, the gains in LEB are modest and likely to depend mainly on other factors discussed later on such as unemployment, the distribution of income, family arrangements, social cohesion, and so on.

Relevant Explanations

Mounting Alcohol Consumption

Official past data suggested that national sales statistics covered less than 50% of real consumption (Tremblay, 1997). Alcohol intake during the transition was thus estimated indirectly based on increases in alcohol-related deaths. This and other indirect methods suggest that alcohol consumption rose perceptibly in several economies in transition (see Shkolnikov and Nemtsov, 1997). In Russia, indirect estimates by Shkolnikov and Nemtsov (1997) showed that average alcohol intake jumped from 11.8 litres per capita in 1989 to 14.5 litres in 1993 and that this increase contributed to a rise in accidental deaths. Likewise, in Poland, per capita consumption rose from 8 to 11 litres between 1988 and 1991, and fluctuated around that level over the subsequent five years. These estimates allowed Moskalewicz et al. (2000) to conclude that 32% of the overall surge in male mortality in Russia over 1990–94 can be tentatively attributed to greater alcohol consumption and that the equivalent figures for Lithuania (1990–94) and Poland (1989–91) were 40% and 27%. Given the fragility of the alcohol consumption estimate, these conclusions have to be taken with a pinch of salt. Indeed, a key issue in this debate concerns the causes of the increase in alcohol consumption (Paniccià, 1997). Possible explanations include: trend inertia reflecting deeply rooted

consumption habits; changes in incomes and the relative prices of alcohol;⁴ a relaxation of the anti-alcohol policy during the transition; and psychosocial stress.

However, the ‘alcohol hypothesis’ does not explain why alcohol related-mortality fell during the successful transition of the Czech Republic and why alcohol consumption remained constant in Poland after 1992. Similarly, in the 2000s, the number of alcohol-related deaths fell in Russia and the Baltics, where there is no evidence of a drop in total alcohol intake, though this was accompanied by a drop in the consumption of hard liquors and a rise in that of beer and wine. Moreover, it cannot explain the huge rise – and subsequent fall – in cardiovascular and other deaths that, while related to stress, are not mediated by alcohol intake. Moreover, in Russia, per capita alcohol consumption and alcohol-related deaths (from external causes, including murders, suicides, and poisoning) moved in opposite directions over 2002–07.

Subsequent analyses have focused on the way alcohol is consumed. While in Mediterranean countries, important amounts of alcohol are consumed every day, mainly with meals, in Russia, Belarus, Ukraine, and the Baltics, the same weekly amount is likely to be consumed on a single occasion, a drinking pattern termed binge drinking. Research suggests that the latter is causally associated with cardiovascular death. However, a study of 25,000 autopsies carried out in Barnaul (Siberia) over 1990–2004 suggests that 21% of adult male deaths attributed to circulatory diseases induced by alcohol consumption were caused by alcohol poisoning, i.e., lethal or near-lethal levels of ethanol concentration in the blood (Brainheard and Cutler, 2005).

Overall, alcohol has likely been an associated factor in 27–40% of the rise in male mortality and in a smaller proportion of female mortality, but fails to explain two-thirds of the rise in male mortality and over nine-tenths of that in female mortality. The main cause of this epochal disaster must therefore still be sought elsewhere.

Acute Psychosocial Stress

Acute psychosocial stress has been increasingly recognised as a key factor in sudden deaths, that is, deaths due to heart problems and hypertension, alcohol psychosis, neurosis, homicide, suicide, accidental deaths, ulcers, and cirrhosis of the liver, that is, the very causes of death that rose in importance during the transition. According to Serafino (1994, cited in Shapiro, 1994),

⁴ In Russia, for instance, the alcohol purchasing power of wages rose by 48% between 1989 and 1993 because of a drop in the price of alcohol greater than that in the average wage. However, a study by Denisova (2010), based on twelve rounds of the Russian Longitudinal Monitoring Survey covering the years 1994–2007 found that while social status, labour market behaviour, sectoral and occupational mobility, and smoking and alcohol consumption had a strong effect on longevity, there was no evidence that the low relative price of vodka led to greater alcohol consumption. Likewise, the meta-analysis of 39 studies on the determinants of the transition mortality crisis Schiering et al., (2018) found no evidence that alcohol consumption and drinking patterns were consistently associated with higher death rates, while Popov (2018) presents several other reasons why an increase in alcohol intake fails to provide a consistent explanation of the surge in transition mortality. Finally, Razvodovsky (2016) analyzed trends in sex-specific suicide rates and alcohol sales per capita from 1980 to 2010 in Russia, Belarus and Ukraine by means of a Spearman’s rank-order correlation analysis. The estimates based on the Soviet period suggest a strong association between alcohol sales and suicide rates in Russia, Belarus, and Ukraine. At the same time, the relationship between alcohol sales and suicide rates was negative in the post-Soviet period. The author concludes also that alcohol cannot fully explain the fluctuations in the suicide mortality observed in these countries during the Soviet period. The similar regional pattern of suicide trends does not support the hypothesis that alcohol policy was responsible for the decline in Russian suicide mortality during the recent decade.

“Stress is the condition that results when person/environment transactions lead the individual to perceive a discrepancy – whether real or not – between the demands of the situation and resources of the person’s biological, psychological or social systems.”

Deaths due to acute psychosocial stress thus entail growing strain and pressures to adapt to unexpected situations for which established individual responses are no longer effective, appropriate coping behaviours are unknown, and the public policy response is inadequate.

Epidemiological research has shown that, in the absence of mitigating factors, acute stress leads to physiological and psychological arousal that affects health status via direct and indirect pathways. Marmot and Bobak (2000) have reviewed the direct effects of stress. They found that stressful situations cause a higher secretion of cortisol, endorphins, platelets, fibrinogens, and fibrinolysis, that is, substances that affect the level of plasma lipids, blood coagulability, blood pressure, cardiovascular reactivity, the development of central obesity, responses to inflammation or infection, and the risk of depression. Chronic exposure to stress has also been found to cause coronary artery atherogenesis and to affect the immune system through a significant suppression of T-cell immune response. Finally, psychosocial stress has been shown to provoke an indirect effect on health via the increased use of stress-relievers such as alcohol, tobacco, and drugs, which influence health and social behaviours, as well as the ability to maintain emotional balance and coherent comportment.⁵

What were the main socio-economic sources of stress during the transition? The first was an unexpected rise in unemployment, employment instability, and rapid labour turnover. Mortality rose most in countries, districts, and years that recorded adverse labour market changes starting with a rise in ‘unexpected unattended unemployment’ and in other adverse labour market changes (Cornia and Panicià, 2000). This confirms the results of controlled studies carried out in Western countries on factory closures and significant lay-offs and follow-up studies on unemployment; that is, studies that replicate quasi-experimental conditions. These have shown that the sudden loss of employment and similar events are a major cause of stress, cardiovascular and mental problems, and death (Beale and Nethercott, 1985; Warr, 1987; Martikainen and Valkonen, 1996). These studies have provided evidence of higher mortality for accidents and violence, alcohol-related diseases, traffic accidents, and circulatory diseases among the unemployed (Smith, 1992). Grouped data for the economies in transition (Cornia and Panicià, 2000) confirm the existence of a strong correlation between the rise in unemployment and other adverse labour market changes and mortality changes in Czech Republic, Russia, Latvia, the former GDR, and Poland.

A specific pathway through which adverse labour market changes emerged in the transition economies concerns the approach followed to the privatisation of state-owned enterprises. A study based on Russian micro-level data by Azarova et al. (2017) uses enterprise and settlement-level data to enable a comprehensive analysis of both underlying and proximate causes of mortality in mono-industrial towns. This retrospective cohort study compares mortality in 10 fast-privatised factories with that in 10 slow-privatised ones. It found that fast privatisation – which is often associated with factory closures and asset stripping – raised workers’ mortality by between 13% and 21% (depending on the model specification used) in relation to slow-privatisation, after controlling for alcoholism, smoking, age, marital status, and financial deprivation. While in Soviet times, SOEs hoarded labour,

⁵ The health impact of stress varies considerably, however, from one person to another due to genetic differences and differences in individual abilities to adjust to new situations.

resisting massive layoffs in slow-privatising SOEs possibly reduced the stress related to sudden unemployment. Being employed, even nominally, provided people with minimal security and gave them the feeling of being in control of their lives. Likewise, before being privatised, SOEs offered a wide range of social benefits to employees and their families in the form of housing, healthcare, day care, and holiday recreation. When these enterprises were privatised, such benefits ended abruptly in the case of fast privatisation, but more gradually in the case of slow privatisation, giving workers the time to adjust to the new circumstances. Municipal authorities were often charged with taking responsibilities for these services but, due to serious financing problems, were unable to adequately fulfil such new obligations.

Through what pathways does unemployment affect health? The most obvious effect is that mediated by the loss of income. Unemployment, however, also affects people in other ways. Indeed, unemployment generates a loss of skills, cognitive abilities, motivation, and the sense of confidence and control (Sen, 1997). Unemployment can also be a source of psychological harm because of the loss of self-respect, feelings of being unwanted, unproductive, dependent, and without a social role, and due to rising anxiety about the future. Unemployment may also erode social norms and cause an increase in crime rates among the jobless. While material deprivation plays a role in the increase in crime, so does the greater sense of exclusion felt by the jobless. Finally, the loss of employment disrupts family and social relations and is associated with mounting alcohol consumption and family violence (ibid). There is also evidence that the impact of joblessness is related to the lack of expectations of becoming unemployed. Indeed, the impact seems to be greater among workers who were permanently employed and had no expectation of being laid off, as happened in many transition countries. It is moderate among workers whose fixed-term contracts are expiring and minimal among those who had never been employed and continue to be unemployed (Björklund and Eriksson, 1995).

Growing Undeserved Income and Asset Inequality

Growing undeserved income and asset inequality, i.e., inequality unrelated to differences in talent, effort, and human capital. Previous analyses of market economies have emphasised the negative correlation between income concentration and health outcomes (Wilkinson, 1996; Kawachi et al., 1999; Pickett and Wilkinson, 2010). Unequal societies are also afflicted by a high incidence of cardiovascular problems caused by low involvement in community life. Rising income and asset inequality may erode social cohesion, that is, the relations of interpersonal trust, mutual insurance, collective action, and redistribution at the local level. Social cohesion enhances health status by promoting the diffusion of health information, exerting control over deviant health behaviour and criminal activity and providing interpersonal help among community members. Finally, health status in an unequal society is also influenced through psychosocial pathways. Strongly hierarchical societies appear to be subject to a high incidence of cardiovascular problems, less social integration, less involvement in community life, and greater personal isolation, which is an important cause of morbidity and mortality.

Several of these effects have occurred in the countries in transition exhibiting rapid rises in social stratification. On one hand, the economies of Central Europe experienced moderate initial increases (4-6 Gini points) in income inequality (Cornia, 2004). These countries contained the fall in the tax/GDP ratio and were thus able to continue financing the social services and benefits inherited from the socialist era and to introduce new provisions (for

unemployment compensation and social assistance) that are needed in a market economy. On the other hand, in the former Soviet Union and South-eastern Europe, the Gini coefficients rose by an astounding 10-20 points, that of the asset distribution by even more, social transfers collapsed, and the targeting of transfers deteriorated (Cornia, 2001). As a result, in 2014, the Gini coefficient of the distribution of gross income was 25-27 in Central Europe – apart from Poland – and 35-41.6 in South-eastern Europe, the Baltics, and Russia (WIDER, 2018).

Third, these distributive changes placed a heavy psychological burden on the losers, namely, middle-aged, unemployed, semi-skilled industrial workers, collective farmers, and party cadres. As the new elites often reached their positions through ascription, capture of state assets, and corruption, the losers experienced rage, hostility, humiliation, lack of recognition, and unwontedness. Disorientation was also acute among the elderly and middle-aged adults who saw the values, norms, and savings of their lifetimes vanish.

Growing Numbers of People Living Alone

At all ages, stress-related mortality is higher among people (men in particular) who are widowed, divorced, separated, or who never married than among those who live in a stable partnership (Martikainen, 1995). The latter presumably lead healthier lifestyles, are less exposed to stress, and have greater access to support networks than people living alone. This regularity was confirmed during the transition, as the percentage of widows and widowers in the adult population rose, the crude marriage rate fell by between 16 and 54%, and the divorce rate edged up until the early 2000s by 10-15% in Russia, Ukraine, Belarus, and Moldova. These are the countries which experienced the most pronounced mortality rises. While even large annual shifts in these rates modestly affect the percentage of people living alone in the total, a continuation of this trend for a decade perceptibly raised the number of single adults who faced higher health risks. In addition, the unmarried-married mortality differential widened further during the transition, contributing in this way to a rise in aggregate mortality. For instance, even in the Czech Republic – which experienced a fall in death rates after 1991 – the risk of death of divorced men relative to married men rose from 2.03 in 1990–91 to 2.27 in 1995 (Dzurova, 2001).

The number of people living alone also rose because the number of divorces rose over 1989–96 and 2000–2003 (Transmonee, 2017). In Russia, the general divorce rate rose from 42.1 to 73.2 per 100 marriages in 2003, the year that recorded the highest number of excess deaths (Annex Table 1). Moreover, Pridemore and Shkolnikov (2004) found that in Russia, homicide mortality was 2.86 times higher among divorced people than among married people, and 9.3 times higher among divorced people with low education versus married people with high education.

Distress Migration

Previous analyses have shown that migrants face greater mortality risks than people who remain in their communities (Eyer and Sterling, 1977). This finding was confirmed during the transition as, after 1989, at least nine million people moved within or between the countries of the CIS alone, seeking work, fleeing conflicts, as political refugees, or returning from abroad. For many of them, migration entailed considerable material hardship, disorientation, and a loss of control due to the difficulties encountered in new environments, the breakdown in

social relationships, the redefinition of survival strategies, housing problems and, as a result of all this, greater stress and, at times, homelessness.

THE IMPACT OF POLITICAL DEMOCRATISATION

A limitation of the above analysis concerns the puzzling differences in national policy responses to the mortality crisis. There is a need therefore to develop an accepted theory of why such responses differed so much among countries. For instance, despite its magnitude, the mortality crisis of CIS countries during the early years of the transition generated a limited response by several incumbent governments, a fact that may raise questions about the degree of democratisation and social concern that prevailed therein. The fact that the crisis hit most marginal groups with no ‘political voice’ may explain why this response was so limited. But other hypotheses may also be explored. Thus, the 16 million excess deaths recorded in Russia, Ukraine, Moldova, and Belarus between 1990 and 2014 still lack a comprehensive political theorisation.

Plotting the trends of LEB and the Freedom House Index of democracy for Russia and Belarus shows that there is a fairly close correlation (at least between 1992 and 2005) between the worsening of the Freedom House Index (FHI) and male LEB.⁶ These two countries experienced a fall in LEB until 2005 in parallel with a worsening in the FHI. In contrast, a similar scatterplot for Poland and the Czech Republic (Figure 1, bottom panel) confirms the close statistical association between the trend in LEB and the FHI. Indeed, in both these countries, these two variables improved, hand in hand, throughout the period analysed.

The same relation was also plotted for all European economies in transition over 1989 and 2014 (Figure 2). Also in this case, it appears that the two variables correlate closely. On the basis of Figure 2 – and pending a more detailed investigation taking care of the problems of endogeneity and variable specification – it appears that countries that introduced truly democratic institutions (scores 1 and 2) enjoy a male LEB of 7-8 years higher than those with a low score.

Public choice theory suggests that when income inequality is high, governments (as well as a self-interested bureaucracies) are likely to implement suboptimal policies that retard the provision of essential pro-growth public services. Rising divergence of interests and types of public services demanded by the rich and the poor leads to an overall drop in the supply of basic public services essential for growth, such as personal security, contracts enforcement, security of property rights, and human capital formation. Indeed, the rich resist taxation as they perceive that the supply of public services funded by an increase in revenue will bring little benefit to them. In extreme cases, the high income groups support policies that preserve their privileges even at the cost of slow or stagnant aggregate growth. The problem is particularly severe when the concentration of income in the upper deciles is accompanied by

⁶ The yearly scores of the Freedom House Index of democracy summarize the subjective values assigned by experts to 10 political rights areas grouped into three subgroups. These cover the electoral process, political participation and pluralism, and the functioning of the government) and 15 civil liberties covering the freedom of expression and belief; associational rights, rule of law, and personal autonomy and individual rights. Such different aspects of democracy are then summarized by means of the arithmetic mean, that ranges between 0 (perfect overall democracy) and 7 (total absence of it).

widespread poverty at the bottom of the distribution, without a middle class capable of challenging politically inefficient government decisions. The Guatemala of the early 2000s, where the tax/GDP ratio was 8% and the coverage of public services minimal, is a good example of this state of affairs (since 2003 taxation has risen and inequality declined, if modestly).

Source: Own elaboration using the index of participatory democracy 'partidem' and Transmones (2017).

Figure 3. Relation between the Participatory Democracy Index (horizontal axis) and male life expectancy at birth (vertical axis) for all transition countries and years with data, 1989-2014.

Because of the criticism that is often addressed to the FHI, and of the problems posed by equating democracy with ‘electoral democracy,’ the relation between ‘political democratisation’ and male LEB was also tested using an alternative indicator that emphasises ‘participatory democracy,’ such as the ‘vdem partidem’ indicator. This index is extracted from the ‘Varieties of democracy V-Dem’ website and is the average of three components: the first is a ‘participatory component index’ that emphasises the active participation by citizens in all political processes, electoral and non-electoral. This index takes suffrage for granted, but emphasises also the engagement in civil society organisations, direct democracy, and the election of subnational bodies. ‘vdem partidem’ includes also a (fairly similar) ‘Participatory democracy components’ indicator that emphasises active participation by citizens in all political processes. The index also includes the level of electoral democracy. And, third, the index includes a ‘Political Participation Rights’ component that measures the extent a country enacts political participation rights by law and respects them in practice. The overall index varies between 0 (no participatory democracy) and 1 (when participatory democracy and participatory rights are fully realised).

As shown in Figure 3, this index identifies very different situations of ‘participatory democracy.’ Some countries (such as Uzbekistan, Turkmenistan, and Belarus) have very low scores of 0.1–0.2; others (especially in Central Europe) have scores of up to 0.65. Russia’s score ranges between 0.27 and 0.32, Ukraine’s between 0.48 and 0.52, and the Baltics between 0.55 and 0.59. Also, in this case, the male LEB difference between the best and worst performers is about 6–7 years, while a considerable amount of variance remains – as expected – unexplained.

There seems, therefore, to be a fairly solid empirical association between electoral democracy, participatory democracy, and civil rights on one side, and male LEB on the other. Beyond differences in the ‘initial distortions’ mentioned in the first part of the chapter, the depth and nature of democracy thus helps explain the different national policy responses to the transitional mortality crisis and – in the end – the losses/gains in male LEB.

The relation between participatory democracy and male LEB is also tested econometrically hereafter over the years 1990–2014 and for the 21 countries included in Table 1 after introducing the yearly GDP/capita in a quadratic form as a control. Indeed, the impact of GDP per capita on male LEB is highly concave, as its effect is strong at the beginning, to decline after about 6,400 1990 international dollars. This relation – known as ‘the Preston Curve’ from the name of the demographer Samuel Preston who first described it in 1975 – suggests that GDP/capita should be introduced in a nonlinear form among the determinants of LEB. Furthermore, an analysis of the scatterplot suggests that the impact of GDP/capita on male LEB was particularly pronounced over the years 1989–2002, and for this reason we introduced a 1990–2002 ‘dislocation dummy’ that turns out to be highly significant in regression.

The results of this econometric test are reported in Table 4. They show that, after introducing as controls the GDP/capita (that has the right sign and is statistically significant at the 1% level) and the ‘dislocation dummy’ 1990–2002 (that is equally statistically significant and with the expected sign), the variable v-partidem is statistically significant at the 5% probability level, while the overall R² is high (0.9). An increase of v-partidem by 0.1 points would raise – *ceteris paribus* – life expectancy by about 0.2 years. For instance, if Russia’s current v-partidem score (about 0.3) rose to that of the Czech Republic (0.65), its male LEB would improve by about 0.7 years. If the analysis were conducted for years prior to 2002, the

favourable effect on male LEB would have exceeded 2 years. The level of participatory democracy therefore influenced the level and trend of male LEB in a non-negligible way, especially for the initial transition years. Of course, the other variables discussed above concur in explaining the large cross-country male LEB gap observed among the European transition economies.

How can one support this conclusion theoretically? An initial argument has to do with asset and income inequality. To start with, in the 1990s, all European countries in transition (apart from the Central Asian countries and Belarus) shifted from a uniform model of authoritarian centralism to different shades of ‘Western-type democracy.’ Yet, in itself, greater ‘electoral democracy’ did not help to improve human wellbeing and health status, unless ‘participatory democracy’ and ‘economic democracy’ improved in parallel and unless the economic base of the disenfranchised populations did not deteriorate.

‘Economic democracy,’ in turn, depends on historical path-dependent factors affecting the current asset and income distribution. In this regard, the very different models of privatisation of state assets followed in the region after the collapse of communism influenced to a large extent the degree of asset concentration in the region, the distribution of political power, and the current level of income inequality. As noted earlier, the current Gini coefficient of income inequality in Central Europe is 40% lower than in Russia.

In this regard, public choice theory suggests that the high-income polarisation observed in the several CIS countries led to a divergence in the types of public expenditure demanded by different income groups. In countries with rising asset concentration, the new elites increased their political ability to resist taxation and influence the allocation of public expenditure towards activities (including prestige items and national defence) that were perceived to benefit them the most, while neglecting public expenditure on health, education, housing, and income support. Greater public expenditure on these items would have substantially benefited the marginal groups hit by the mortality crisis. Yet, the elites perceived such expenditures would have brought little gains to them. Indeed, where asset and

income polarisation rose, the state provision of educational and health services declined, or was privatised, while residential segregation increased. Elite-friendly governments neglected the health needs of the masses when deciding resource allocation, reducing in this way the prospects of the poor and of the middle-class for achieving adequate income levels and effective access to public healthcare. What is observed in the region may therefore confirm the conclusions of the literature that suggests that when asset and income inequality are high, governments and self-interested bureaucracies are likely to implement suboptimal policies that retard or reduce the provision of essential pro-poor and pro-growth public services. Rising divergence about the types of public services demanded by the rich and the poor often lead to an overall drop in the supply of basic public services that are essential for growth, such as personal security, contracts enforcement, and human capital formation.

A second way through which high inequality may affect health status is that the 'procedural democracy' and formal political freedom typical of polarised societies may not guarantee 'political stability' and health-enhancing social cohesion. During the communist period in much of the former Soviet Union, official organisations affiliated to the Communist Party, such as the Pioneers and sport and leisure associations, took the place of civil society organisations that had developed spontaneously in the West, or that had not disappeared during the communist era. This is the case of trade unions and church organisations in Poland, cooperatives in Hungary, or pre-communist institutions (such as neighbourhood associations like the Mahallas in Uzbekistan and similar groups in Armenia).

The preponderant role of the Communist Party and the limited scope for independent self-organisation generated a deep-rooted apathy among individuals and led, after the political liberalisation and subsequent collapse of the Communist Party, to the creation of a 'shallow democracy.' This lacked a well-developed network of civil society organisations (associations, NGOs, and churches working in the social sphere, trade unions, producers' associations, and self-governing bodies). These organisations help the formation and channelling of political consensus, democracy at the local level, defence of the interest of marginalised populations, and active political participation, i.e., all institutions and organisations that would have likely helped to contain the increase in mortality. For instance, a study on Russia (Stuckler et al., 2009) found that every one percent increase in the share of the population who were members of at least one social organisation decreased the associated risk of mortality by 0.27%. When more than 45% of the population surveyed was socially organised, the mortality differential with privatisation was no longer there.

CONCLUSION

The eruption of a massive transformational mortality crisis following the introduction of market reforms that were expected ex-ante to generate positive economic, social, and health effects confirms that poorly managed societal transformations may generate acute deteriorations in the economic and health spheres. The 35% increase in male suicides over 2007–2011 recorded in Greece during the recent years of austerity (that in the view of the EU and IMF was to lead to a rapid economic turnaround) provides another example of the need to adopt measures to control the rise of instability, unexpected job losses, inequality, and personal insecurity. Swift policy responses in these areas are needed both for the specific

benefits they produce (e.g., better labour market outcomes) as well as because of their positive health impact.

Acceptance of the psychosocial stress explanation has important policy implications. Supporters of 'big bang policy reforms' tend to ignore the social and health impact of such reforms, to ascribe them to problems inherited from the past or to the unavoidable chaos brought about by profound political transformations, and to suggest that there are no quick fixes for such problems. Meanwhile, conservative forces (like the unreformed neo-Soviet parties) argue that the mortality crisis has been caused by the sheer impoverishment brought about by the introduction of capitalist institutions, and that most liberal reforms (including privatisation) should thus be reversed or drastically amended.

The implications of the analyses presented in this chapter are substantially different from either of these two views. Vigorous market reforms are necessary. But – as shown by the case of the Czech Republic and Poland or by the gradual two-track price liberalisation followed in China over 1978–84 – they need to be characterised by a realistic pace of restructuring and privatisation, strong labour market and social sector policies, maintenance of law and order, and the strengthening of healthcare. To finance all this in a non-inflationary manner it is necessary to generate adequate revenue.

A solution to the mortality crisis that has affected the countries of the former Soviet bloc will require vigorous measures to prevent or control transition-related psychosocial stress. Measures needed under such circumstances include properly paced macroeconomic adjustment and industrial restructuring, adequate credit and technical assistance policies for small firms, job re-training, public works, unemployment compensation, wage subsidies, and measures to contain surges in inequality, social exclusion, family breakdowns, and distress migration. Deaths due to violent causes and infectious diseases can also be avoided by strengthening the police and social assistance services dealing with people marginalised by the crisis. A stricter regulation of alcohol consumption and other stress relievers is also needed to reduce violent and cardiovascular deaths. Reversing the negative long-term trend in health status will also require efforts at improving lifestyles, educating people about the risk of smoking, poor diets, and excessive drinking, and a strengthening of preventative and curative healthcare, especially in the case of heart problems. Initiatives in this area would have the double advantage of reducing the rise in violent deaths (thanks to better policing, efficient deterrence by the courts, and active assistance for and control of marginalised groups) and of containing overall stress by improving security. Greater regulation of alcohol consumption will also be needed to reduce violent deaths, cirrhosis, and throat cancer. This can be accomplished through higher alcohol prices, a reduction in the number of outlets, reduced opening hours and reduced sales to minors (key measures which require strong government commitment), and educational campaigns aiming at modifying drinking behaviour.

Chapter 289

MORTALITY CRISIS IN RUSSIA REVISITED: EVIDENCE FROM A CROSS-REGIONAL COMPARISON

Vladimir Popov*

Dialogue of Civilizations Research Institute, Berlin, Germany

INTRODUCTION

This chapter attempts to present a cross-regional comparison to analyse the Russian mortality crisis of the 1990s; the mortality rate increased from 1.0% to 1.6% in 1989-1994 and remained at a level of 1.4-1.6% thereafter. Mortality peaked in 2003-05 before beginning to subside (Figure 1), and we now have a full dataset with which to examine the dramatic upsurge in mortality from the beginning to end. I argue that the drastic increase in mortality during the first half of the 1990s was only weakly associated with deterioration of the healthcare system. The jump was instead largely due to stress-related factors (e.g., increased labour turnover, migration, divorce, and income inequality) along with an increase in unnatural deaths (e.g., murders, suicides, and accidents) and somewhat less attributable to alcohol consumption during the transition. Cross-regional differences in healthcare facilities (e.g., the number of doctors, nurses, and hospital beds) did not exert much influence on life expectancy. After the collapse of the free healthcare system in the Soviet Union, legal and illegal user fees became common in the 1990s and beyond. The poor segment of the population could thus not take advantage of healthcare facilities regardless; essentially, health infrastructure only positively affected life expectancy in regions with marked income inequality (i.e., regions with a large share of the highest-income group).

STYLISTED FACTS AND THEORIES

The transition to a market economy and democracy in the 1990s in Eastern Europe and former Soviet Union countries led to a dramatic increase in mortality and shorter life expectancies, resulting in depopulation. Notably, output fell by 45% in 1989-1998, and social

* Corresponding Author's Email: VPopov@doc-research.org.

indicators (e.g., rates of crime, murder, suicide, and income inequality) declined sharply as well. Mortality in Russia increased to levels unlike those of the 1950s-1980s; that is, such rates had been unprecedented for at least 40 years (Figure 1). One must go as far back as 1940 to find mortality rates higher than those in 1995-2005; data for the 1941-49 period (the Second World War and post-war reconstruction) are unavailable.

The 1990-2003 fall in life expectancy was truly exceptional. Russia's transition story was associated with comprehensive market-type reforms, which added another shock to the shock of democratisation. Price deregulation and ensuing changes in relative prices led to a mass reallocation of capital and labour that contributed greatly to stress-related factors: increased rates of unemployment, migration, labour turnover, divorce, and income inequality. However, the general rule was that countries with stronger institutions, whether democratic (e.g., Eastern Europe) or authoritarian (e.g., China and Vietnam), managed to cope with stress-inducing factors better than others. Moreover, only authoritarian regimes (China is the top example) managed to choose and implement a gradual transition strategy wherein the necessary restructuring - reallocation of capital and labour - could be stretched over a considerable period and thus alleviate the stress associated with unemployment, migration, and labour turnover (Popov, 2006, 2007).

As a rule, countries that proceeded with more gradual reforms (from China to Uzbekistan and Belarus) also managed to preserve their institutional capacity and completely avoid, or at least mitigate, a collapse in output and increase in mortality (Popov, 2000, 2007).

Several theories in the literature have delineated reasons behind the mortality crisis in Eastern European countries and former Soviet republics (see Chapter 1). Relevant factors include a decline in food consumption due to economic hardship, deterioration of the healthcare system, the stress associated with transitioning to a market economy and democracy, increased crime and accidents, pollution, increased alcohol and tobacco consumption, the 'demographic echo' (see survey in Chapter 2; Cornia, 1997, 2004; Cornia & Panicià, 2000). More recently, these theories were reduced to two: stress and alcohol. Numerous other explanations, such as accidents, crime, nutrition, a deteriorating healthcare system, and smoking, definitely played distinct roles; for instance, per-capita sales of cigarettes in Russia in 1996-2006 doubled due to free advertising.

Source: Goskomstat.

Figure 1. Mortality and life expectancy in Russia (1922-1991 [USSR]), 1913-2014.

Yet these factors cannot explain several trends: the rapid and steep rise in mortality (there should be a lag with regard to increased smoking, poorer nutrition, and declining healthcare services); the magnitude of the crisis (additional annual deaths due to increased mortality in the 1990s totalled about 1 million per year in Russia alone, whereas total additional deaths due to murders, suicides, and accidents were lower by an order of magnitude - about 100,000); and the predominantly cardiovascular causes behind the increased death rate (i.e., a dramatic increase in mortality from such diseases among 40-to-50-year-old men).

Cross-regional comparisons for the Russian Federation, drawing from data on about 80 regions, can shed light on major drivers of the mortality crisis. The most successfully performing regions, such as resource regions, demonstrated high employment elasticity in terms of output along with relatively (as measured against the magnitude of reduced output) high unemployment rates (Popov, 2001a). Such a pattern suggests a likely trade-off between performance and employment downsizing, with a price to pay for better performance in the form of a higher relative increase in unemployment (per unit change in output) due to restructuring (Gaddy & Hill, 2003; Korel & Korel, 1999). In absolute terms, unemployment levels in better-performing regions were quite close to the national average despite more favourable output dynamics. Another 'cost of success' came in the form of higher labour mobility and growing income inequality. The Gini coefficient of income distribution did not seem to depend on performance: regions with smaller declines in industrial output in the 1990s did not exhibit lower income inequality. As a result, regions that were relatively better off in terms of output change were relatively worse off in terms of stress-related factors, leading to higher increases in mortality and greater reductions in life expectancy (Walberg et al., 1998).

DATA AND METHODS

The dependent variable is the change in life expectancy in 1990-2003¹. Unlike the mortality rate, life expectancy does not depend on the age structure of a population, leading to one less factor to control for when seeking explanations. Relevant explanatory variables can be divided into three groups:

1. Objective conditions (climate, proxied by average January temperature; degree of urbanisation; population density; and Far East and Moscow dummy variables).
2. Economic variables (investment and income) and indicators of regional governments' institutional capacity (increase in murder rates; share of small

¹ Russia's mortality crisis primarily consisted of increasing mortality among working-age individuals. Mortality in individuals younger than age 15 and older than age 70 (women) declined after 1991. Life expectancy at birth is affected by mortality during working age, by infant and child mortality, and by old-age mortality. As a result, changes in life expectancy at birth are confounded by changes in child mortality having the opposite direction than during adult ages. Hence, age-adjusted mortality during working age (15-60 or 20-60 years old) or life expectancy during working age may be a better mortality indicator when studying the Russian mortality crisis. However, data on age-adjusted mortality during working age (15-60 or 20-60 years) or life expectancy during working age were unavailable in the regional breakdown. Instead, I introduced another independent variable: the share of population at working age in 1998 (the middle of the study period). This variable was insignificant in all specifications. One could also argue that stress and alcoholism affect the elderly and children as well - the elderly for obvious reasons, and because children in stressed families with high alcohol consumption are exposed to greater health risks.

enterprises in regional employment, adjusted for degree of urbanisation). Murders clearly affect mortality directly, but they are also good indicators of the state's institutional capacity (monopoly on violence - see Popov, 2001a, 2001b, 2007). The share of small enterprises in total employment characterises the regional government's ability to create a business environment rooted in law and order (Popov, 2001a, 2001b). This institutional capacity is necessary to manage restructuring and associated stress.

3. Stress-related indicators (increases in labour mobility and unemployment, migration, divorce, income inequality, and poverty).
4. Level of alcohol consumption and associated increase.
5. Healthcare system deterioration, proxied by the change in the number of doctors per capita.
6. Political orientation of regional governments, proxied by the percentage of votes received by communists during elections in the 1990s.

All indicators were taken from Goskomstat (Regiony Rossii) unless otherwise specified. The Goskomstat database contains data on 89 regions, but not all data were available for each region. Increment indicators capture the period under investigation (1990-2003) except for the following. The increase in per-capita vodka sales was measured from 1997 to 2003 because there were no data; the same applies to the increase in poverty level (1994-2003), increase in inequality (the ratio of the share of 20% of the wealthiest population to the share of 20% of the poorest population in total income; 1995-2003). The change in regional investment (compared to the Russian average) was measured from 1990 to 1998, as 1998 was the lowest point of investment decline in most regions. The change in real income was measured from 1990 to 1999 because the trough in real incomes occurred in 1999, the year following the currency crisis of August 1998 that led to dramatic devaluation of the Soviet ruble and a reduction in real income. Investment and real income each recovered after 1998-99, but this gradual (and incomplete, in the case of investment) recovery was allegedly less important to the change in life expectancy than the sharp reduction during the first half of the 1990s².

Level indicators refer to the middle of the period in question (i.e., 1997). An exception is the labour turnover variable, which was only available for 1995. The unemployment level variable for 2003 was used in the regression to explain the increase in alcohol sales in 1997-2003. The share of votes cast for communists was measured based on the results of the 1996 presidential election, but other elections in the 1990s were not drastically different in this respect (Figure 2).

AVTEMP, the average temperature in January 1997, had a predictable negative effect on life expectancy change, suggesting that it was more difficult to contain the rise in mortality in cold regions due to collapsing infrastructure during the transition. URB, the share of the urban population on January 1, 1997, had a negative impact on life expectancy because economic restructuring was occurring mostly in urban areas. FAREAST, a dummy variable for Far East regions, perhaps surprisingly influenced life expectancy positively - presumably because the largely migrant population in this region (virtually everyone was a migrant in the second and third ancestor generations) retained a greater capacity to cope with stress-related factors. MOSCOW, the Moscow dummy variable, had a negative impact on the change in life

² This assumption was tested and confirmed.

expectancy; the magnitude of restructuring in this city was the highest in the country, and stressors were numerous.

Source: Central Electoral Commission, Russian Federation. The list of variables can be found in the Appendix.

Figure 2. Percentage of votes cast for the Russian Federation Communist Party in various elections in the 1990s.

INVincr, investment in 1998 as a % of 1990, had a predictable positive impact due to better infrastructure and job prospects. Yincr, representing personal real income in 1999 as a % of 1990, had a negative impact on life expectancy, suggesting that stress played a prominent role in influencing changes in mortality, such that regions with higher growth in real income (i.e., more rapid restructuring) paid a high price in the form of greater increases in mortality.

Institutional capacity indicators had predictable (positive and negative, respectively) effects on life expectancy. SMent, the share of small enterprises in total employment in 1997 adjusted for the degree of urbanisation (the higher the share, the better the regional business climate), affected life expectancy positively. CRIMEincr, the increase in the crime rate in 2003 compared to 1990, and HOMIClevelINCR, the increase in the number of murders per 1,000 inhabitants in 2003 compared to 1990, affected life expectancy negatively - both directly (through greater mortality from crimes and murders) and indirectly (as shown by proxies for regional governments' deteriorating capacity to cope with stress-related factors) - and served as proxies for stress factors (i.e., insecurity) in and of themselves.

Stress-related factors had the greatest effects on changes in life expectancy. Specifically, the following factors negatively and significantly influenced changes in life expectancy: labour turnover (i.e., hiring and layoffs) as a % of employment (LABmob); the Gini coefficient of income inequality in 1997 (GINI97); the share of the richest 20% of the population in total income in 2003 (SHrich03); the share of the poorest 20% of the population in total income in 2003 (SHpoor03); the ratio of the share of the richest 20% to the share of the poorest 20% of the population in 2003 (INEQ03); the increase in the number of immigrants arriving in the region per 10,000 inhabitants in 2003 compared to 1990

(MIGRgrINCR); and the increase in the number of divorces per 1,000 inhabitants in 2003 compared to 1990 (DIVrateINCR).

The Gini coefficient considers the deviation in income shares across all income groups from the absolutely even income distribution line and therefore provides a more accurate assessment of inequality compared to the share of the 20% richest and 20% poorest population in total income. However, Gini coefficients for regions of interest were only available for 1997; they were not taken from Goskomstat, which does not report regional Gini coefficients, but from Shevyakov and Kyruta (1998). So as not to waste this information, I considered it alongside other indicators of income inequality.

To potentially shed light on major causes of the increase in mortality, I ran cross-regional regressions. I first regressed changes in life expectancy on all available explanatory variables: objective conditions, economic restructuring and institutional degradation, stress-related indicators, vodka sales, healthcare system deterioration, and regional governments' political orientation. All variables were significant when added separately, although some were correlated. An increase in vodka sales was strongly associated with labour mobility and other stress-related factors. If an increase in alcohol consumption was also driven by stress factors, such as the growth of unemployment, labour mobility, migration, and inequalities, then it would be reasonable to consider residuals from the equation explaining alcohol consumption and then use these residuals as an explanatory variable in the equation for life expectancy change. Doing so would help test whether the exogenous (i.e., not stress-driven) increase in alcohol consumption affected life expectancy.

RESULTS: INITIAL CONDITIONS, ECONOMIC RESTRUCTURING, STRESS, AND ALCOHOL CONSUMPTION

Overall, initial and objective conditions (i.e., climate, urbanisation, and regional dummies for the Far East and Moscow), regional governments' institutional capacity (i.e., share of employment at small enterprises, crime rate, and murder rate), economic indices (investment and income), stress-related factors (labour turnover, migration, divorce, income inequality, and crime), and healthcare system developments (even without alcohol consumption indicators) explained more than 80% of regional variations in changes in life expectancy in 1990-2003 (Table 1).

Alcohol Consumption

Increased alcohol consumption evidently contributed to the rise in deaths due to external causes (i.e., accidents, murders, and suicides). In 2002, death rates from external causes in Russia were the highest in the world (Table 2). Alcohol consumption was also correlated with death rates from all causes, but this relationship does not necessarily imply causation. As was pointed out in Chapter 1, there are some important inconsistencies in the dynamics of alcohol consumption and mortality.

Adjusted R ²	60	80	81	83	83	84	85

*, **, *** Significant at the 10%, 5%, and 1% level, respectively.

Cross-regional comparisons present an additional argument. There is a negative relationship (Figure 3) between the levels of vodka consumption and the level of life expectancy by region: high vodka consumption and low life expectancies in Northern and Eastern resource regions (with extensive restructuring and great stress) compared to low vodka consumption and high life expectancies in southern regions, especially in the North Caucasus (with low levels of restructuring and less stress). Again, one possible explanation would be that higher alcohol consumption leads to higher mortality (lower life expectancy), but the other explanation is that higher stress has two effects - it reduces life expectancy and drives up alcohol consumption, which by itself does not contribute to higher mortality.

A closer look reveals that VODKAincr, which indicates the increase in vodka sales per capita in 1997-2003, was not significant when added into the right-hand side (RHS) of the equation. The level of vodka consumption - VODKA03, per-capita vodka sales in dekalitres in 2003 - affected changes in life expectancy negatively. This pattern was likely due to the variable's correlation with stress-related indicators, particularly with labour mobility (Figure 4); thus, including both variables on the RHS of the same regression could make LABmob insignificant (see the last equation in Table 1). When vodka consumption was included separately, without other control variables (labour mobility, crime rate increase, real income change, and share of employment in small enterprises), it was significant (see Table 1).

The high correlation between labour mobility in 1995 and vodka consumption per capita in 2003 ($R = 0.58$) may have simply been spurious, as the association with vodka consumption in 1997 was only 0.26 and 0.38 with the increase in vodka consumption in 1997-2003. However, the increase in vodka consumption may have also been driven by the same stress factors that contributed to higher mortality. After controlling for population density (POPdens) and the level of vodka sales in the beginning of the 1997-2003 period (VODKA97), 50% of the cross-regional variation in VODKAincr (i.e., the increase in per-capita vodka sales in 1997-2003) could be explained by exactly the same stress indicators discussed previously: the unemployment level in 2003 (UNEMPL03); labour turnover in 1995 (LABmob; no data for later years); increase in migration inflows to the region in 2003 compared to 1990 (MIGRgrINCR); increase in inequality, namely the ratio of the richest group to the poorest in 2003 compared to 1995 (INEQincr); and increase in the share of the population living below the poverty line in 2003 compared to 1994 (POVERTYincr).

Source: Goskomstat.

Figure 3. Life expectancy and sales of vodka per capita in Russian regions.

The following equation best explains changes in vodka sales in 1997-2003:

$$\begin{aligned}
 VODKAincr = & -1.2 - 0.65VODKA97 + 0.002POPdens + 0.03UNEMPL03 + \\
 & +0.001MIGRgrINCR + 0.01INEQincr + 0.04LAEmob + 0.002POVERTYincr \\
 & (3.88) \quad (-3.74) \quad (2.90) \quad (1.97) \\
 & (2.49) \quad (1.66) \quad (6.40) \quad (1.69)
 \end{aligned}
 \tag{1}$$

(N = 75, R² = 0.49; robust standard errors, t-statistics in parentheses; all coefficients significant at the 10% level or better)

A similar equation can explain the level of vodka consumption in 2003:

$$\begin{aligned}
 VODKA03 = & -0.6 + 0.001MIGRgrINCR + 0.03INEQ03 + 0.043LAEmob + 0.01URB \\
 & (2.58) \quad (1.76) \quad (1.76) \quad (4.49) \quad (2.43)
 \end{aligned}
 \tag{2}$$

(N = 79, R² = 0.41; robust standard errors, t-statistics in parentheses; all coefficients significant at the 10% level or better).

When the residuals from the above two equations (explaining changes in vodka sales and level of consumption, respectively) were introduced into the RHS of the best equation to explain changes in life expectancy, these residuals had predicted (negative) sign and were statistically significant. In other words, regional variations in alcohol consumption, even when not determined by stress-related factors, adversely affect life expectancy. However, this impact appeared rather modest: the coefficient linking life expectancy change in years and vodka sales per capita in dekalitres was about 0.5; that is, for life expectancy to fall by 1 year, vodka sales per capita must increase by roughly 20 litres per year. Clearly, the size of the effect was too small to explain the decline in life expectancy by 5 years on average with average vodka sales of 14-15 litres.

Deterioration of the Healthcare System

The impacts of healthcare system developments on life expectancy were rather weak and could not be traced when including indicators of healthcare system capacity (i.e., number of doctors, mid-level medical personnel, hospital beds, and polyclinics' patient capacity) as linear variables on the RHS. This pattern echoes that noted by King, Stuckler, and Hamm (2006). However, when the number of doctors per capita was interacted with the inequality variables and communist vote variable, the coefficients became significant. Equation #6 in Table 1 is best in this case and is presented below to render the impact of the number of doctors explicit:

$$\Delta LE = CONST + CONTR + DOCT03(.0007 COMMvote + .006 SHrich03 - .28)$$

(all coefficients, including control variables, are significant at 10% or less, $R^2=0.84$, $N=63$),

Where

DOCT03 – number of doctors per 10,000 inhabitants in 2003,

SHrich03 – share of richest 20% of the population in total income in 2003,

COMMvote – share of votes cast for the communist candidate at 1996 presidential elections, % (strongly correlated with the share of votes cast for communists at other presidential and parliamentary elections – see “data and methods” section).

(3)

This regression has a threshold, as the equation implies that the number of doctors per capita positively influenced changes in life expectancy only under certain conditions: (1) when the share of the highest income group was sufficiently high (i.e., nearly 40% or over); and (2) when the share of votes cast for communists was sufficiently high. The interpretation of this threshold is rather straightforward: a high healthcare facility capacity exerted a favourable impact on life expectancy only if there were enough rich people in the region who could afford to pay for such healthcare and/or if the regional government was distributing healthcare services in an egalitarian manner (proxied by the communist vote variable). In fact, the coefficient of the COMMvote variable was so small that it could not counteract the inequality effect when the share of the richest 20% in total income was lower than 35%; in this case, the impact of the greater number of doctors on life expectancy was consistently negative, even if 100% of voters voted for communists.

Overall, in 1990-2003, healthcare facilities in Russia contributed to the increase in life expectancy only in regions with very high income inequality (i.e., high shares of the richest income group in total income); in other regions, the impact of a greater number of doctors per capita on life expectancy was negative if this variable had any effect at all. One should note that there were only 10 regions in 2003 where the share of the top 20% of the population in total income exceeded 45% - a necessary condition to enjoy the positive impact of a higher number of doctors on life expectancy (given the actual percentages of votes cast for communists). Furthermore, the impact of healthcare system capacity on life expectancy change was extremely modest compared to the effects of stress-related factors, which clearly dominated.

CONCLUSION

To reiterate, the Russian mortality crisis of the 1990s was caused by a shock-therapy-type marketisation of the economy that led to mass reallocation of labour over the course of industrial restructuring and to a dramatic rise in various stress-related factors - income inequality, unemployment, labour turnover, migration, crime, and divorce - that were largely responsible for an unprecedented 60% increase in mortality. Alcohol consumption, although strongly correlated with a rise in mortality, was likely not an important driver behind this increase but was instead determined by the same stress factors as the rise in mortality rate itself. Deterioration of healthcare facilities only had a modest impact on life expectancy, and solely in regions with a small rich population and non-equitable political orientation (i.e., a low share of votes cast for communists).

Source: Goskomstat (Regiony Rossii) and author's calculations.

Figure 4. Predicted (with and without stress) and actual changes in life expectancy in Russian regions in 1990-2003 (years).

Therefore, the roles of stress factors in this sharp rise in mortality is predominant. Consider predicted changes in life expectancy (according to the regression equation in the second-to-last column in Table 1) and hypothetical changes that would have occurred if stress-related factors were absent (i.e., no increases in crime and homicide rates or in migration, labour turnover, divorce, and income inequality). These two indicators (i.e., predicted changes in life expectancy with and without stress-related factors) are plotted in Figure 4 against actual changes in life expectancy shown on the horizontal axis. Excluding stress-related factors, life expectancy would have been higher by 2003 in every region by roughly 5 years on average. In fact, without these factors, life expectancy figures that had fallen by anywhere from 9 to 0.1 years (5 years on average) in 1990-2003 would have increased in all regions except for 15; thus, on average, life expectancy would have been 1 to 2 years longer in 2003 than in 1990. To be sure, this would not be a great record for 13 years, but at least no reduction in life expectancy would have actually occurred.

APPENDIX

List of Variables

AVTEMP	-	average temperature in January 1997
COMMvote	-	share of votes cast for communist candidate in 1996 presidential election, % (strongly correlated with share of votes cast for communists in other presidential and parliamentary elections)
CRIMEincr	-	crime rate in 2003 as a % of 1990
deltaLE	-	increase in life expectancy in 1990-2003, years
DIVrateINCR	-	increase in number of divorces per 1,000 inhabitants in 2003 compared to 1990
DOCT03	-	number of doctors per 10,000 inhabitants in 2003
FAREAST	-	dummy variable for regions of the Far East
GINI97	-	Gini coefficient of income inequality in 1997 (unofficial estimate; Shevyakov & Kyruta, 1998)
HOMIClevelINCR-		increase in number of murders per 1,000 inhabitants in 2003 compared to 1990
INEQ03	-	ratio of share of richest 20% to share of poorest 20% of population in 2003
INEQincr	-	ratio of richest 20% to share of poorest 20% of population in 2003 minus the same ratio in 1995
INVincr	-	investment in 1998 as a % of 1990
LABmob	-	labour turnover (hiring and layoffs) as a % of employment in 1995
MIGRgrINCR	-	increase in number of immigrants to the region per 10,000 inhabitants in 2003 compared to 1990
MOSCOW	-	dummy variable for Moscow
POPdens	-	population density in 1997, persons per 1 sq. km.
POVERTYincr	-	percent of people below the poverty line in 2003 minus the same percent in 1994, per person
SHpoor03	-	share of poorest 20% of population in total income in 2003, %
SHrich03	-	share of richest 20% of population in total income in 2003, %
SMent	-	share of employment at small enterprises (adjusted for share of urban population in the region) in 1997
UNEMPL03	-	level of unemployment in 2003, %
URB	-	share of urban population on Jan. 1, 1997
VODKA03	-	sales of vodka in dekalitres per capita in 2003
VODKA97	-	sales of vodka in dekalitres per capita in 1997
VODKAincr	-	increase in sales of vodka in dekalitres per capita in 1997-2003
Yincr	-	personal real income in 1999 as a % of 1990

Chapter 290

THE PATH OF ECONOMIC DEVELOPMENT AND HEALTH STATUS: EVIDENCE FROM CHINA

Yue Teng^{} and Luca Bortolotti[†]*

University of Florence, Italy

INTRODUCTION

The last two decades of the 20th century witnessed a wave of deep, radical socioeconomic restructuring in (former) socialist countries (or communist countries in more Western terminology) in Central and Eastern Europe and East and Southeast Asia. The transition from a centrally planned political-economic system to a market economy and, at least, a de jure democracy fundamentally changed not only the political and economic profiles of countries in question but also the welfare of individuals living in those countries. Such a transition was presented by the supporters of the Washington Consensus as a rapid shift from low to high socioeconomic equilibrium. However, without appropriate governance and management, abrupt and uncontrolled transition can lead to huge socioeconomic costs, especially through unattended unemployment, loss of social status, and social stress (Cornia, 2004; Chapter 2). Indeed, the transition led to severe economic recession and social chaos in countries such as the former Soviet Republics, which followed so-called ‘shock therapy.’ Consequently, the biological and psychological welfare of the population (e.g., living standards and health status) experienced a substantial regression and failed to revive even one decade after the collapse of the socialist regime. Russia’s gloomy record of rising mortality, declining life expectancy, and deteriorating lifestyle is the most typical example of such effects in the literature. Apart from problematic economic reform, the absence of strong political institutions, due to the lack of either Central Europe-type effective democracy or China-type effective authoritarian control, serves as another contributor to health recession and stress during the transition (see Chapter 1).

On the contrary, (former) Asian socialist countries, except for Mongolia (which is similar to the Central and Eastern Europe case) and North Korea, have followed a gradualist approach towards political-economic reform. In 1978, China initiated its ‘Reform and Openness’ effort, and the Vietnamese and Lao counterpart (‘Renovation and Openness’) started in 1986. Under the gradualist approach, East Asian socialist countries have avoided the socioeconomic recession that occurred in former Soviet Republics and have instead experienced rapid economic growth since the 1980s (the 1990s for Vietnam and Laos). In particular, the case of China has been widely perceived as an economic miracle with the most rapid and vast poverty reduction in human history. Since 1978, China’s GDP per capita has grown by 8.4% annually on average. In 1978, China’s GDP per capita (2010 constant International Dollar) ranked fourth from the bottom, only marginally higher than Myanmar, Burundi, and Nepal;¹ by contrast, China’s GDP per capita ranked between 70th and 80th globally in 2018.²

Given the substantial success of economic growth and liberalisation, the extent to which the transition has influenced individual welfare in China is of great interest. Indeed, the peculiar institutional framework and political orientation of this country represent a radically different approach to the ‘shock therapy’ transition of the former Soviet Union. Despite China’s unprecedented economic growth, the extent to which the benefits of such growth have translated into better human welfare remains controversial. Whilst Chinese life expectancy today is approaching the (stagnating) level of the United States (see Chapter 3), initial stages of the reform indicate much poorer outcomes that vary widely across social groups. Lu (2006) concluded that the health status of the Chinese population during the reform years was at best mixed at least until the early 2000s, and the state’s withdrawal from healthcare and the consequential marketisation of healthcare have led to this mixed outcome.

This chapter aims to trace the evolution of health status in China during the reform period, namely from 1978 until the present, placing China’s case in a global comparison with other world regions and examining the situation across regions within China. In particular, we follow Wang (2008) and Lo (2016a) in dividing China’s economic reform in the past 40 years into three *de facto* distinct phases based on the policy orientation towards the role of the state in the economy and the progressivity of the policy regime. We then explore the evolution of health status and healthcare in China within these three periods. From the beginning of the reform in 1978 until 1992, the state maintained a dominant role in not only the economy but also broader socio-political spheres. Despite increasing marketisation in many areas of the economy (e.g., the product market, labour market, and capital market), market forces have not completely ‘invaded’ non-economic spheres (Wang, 2008). The continuation of the strong presence of the state and the egalitarian institutional arrangement allowed, to a certain extent, some improvements in the welfare of most of the population during this period. Then, from 1993 to 1999, China adopted a neoliberal reform and followed a market-friendly (but labour-unfriendly) pattern via privatisation of state-owned enterprises (SOEs) and by laying off SOE employees for efficiency (减员增效, *jian yuan zeng xiao*). The state substantially withdrew from most socioeconomic spheres, and market force eventually ‘invaded’ most social spheres. The state largely discarded the egalitarian ideology and passed a substantial part of the

¹ However, it should be noted that GDP per capita did not fully reflect the real level of welfare and economic development for China’s centrally planned economy in 1978.

² The actual rank depends on which country list is used.

provision of public service, especially education and healthcare, onto the market. The burden of education and healthcare was therefore shouldered by individuals, resulting in rampant social inequality (Duckett, 2007; Wang, 2008). Market fetishism led both the state and society to prioritise economic growth over welfare. As a result, by the end of the 1990s, China had transitioned from a high-welfare country to a low-welfare country. Since the early 2000s, China has shifted to a state-led development path and has been approaching the so-called ‘Golden Age’ model, similar to what took place in developed countries between the 1950s and early 1970s (Lo, 2016a). This model features significant state involvement in public service and strong economic performance driven by capital-deepening industrialisation and technological and skill upgrading, leading to the growing provision of public service and improved labour welfare and rights. The institutional arrangement of this model can be summarised as ‘Big Business, Big Labour, and Big Government’ (Lo, 2016a). Underlying this model is China’s ongoing economic rebalancing away from a labour-intensive growth pattern. In contrast to the 1990s, China’s growth path since the 2000s has reconciled economic growth and social development (Lo, 2016a).

The three growth models represent *de facto* orientations towards the role of the state in public service and welfare. The progressivity of the policy regime is higher in the third phase than the first two phases. The three models/phases are also associated with different state capacities to provide public services. Therefore, the three model/phases can be conceptualised as ‘a proactive state with limited resources available for public service’ (1978–1992), ‘a passive state with limited resources available for public service’ (1993–1999), and ‘a proactive state with sufficient resources available for public service’ (2000–now). Having identified the three models/phases, we can next examine how the role of the state in healthcare has evolved under these models/phases and consider how health status has consequentially evolved.

This chapter is organised as follows. Section 2 briefly reviews China’s economic reform and health policy during the three models/phases since 1978. Section 3 presents the evolution of health status as measured by various indicators of healthcare, mortality, and life expectancy at macro and micro levels; the section also includes various econometric estimates to individuate socioeconomic determinants of health status and its trends across Chinese provinces and individuals during transition. Section 4 introduces the concept of comparative political economy to discuss the impact of China’s peculiar transition strategy on the country’s health status, characterised by a competition-driven local developmental state and the consequential low-wage and labour-repressed regime. Section 5 concludes this chapter.

REFORM AND HEALTH POLICY IN CHINA

Beginning in 1978, Beijing started to reform its economic guidelines, gradually and pragmatically, and transformed from a centrally planned economy into a ‘socialist market economy.’ The literature on China’s development suggests various alternative schematisations of the reform period since 1978, depending on whether the focus is on economic targets, domestic events, or international relations (Biggeri & Gambelli, 2008; Wang, 2008; Zhu, 2012). For simplicity, this chapter divides China’s reform into three periods as discussed above.

The reform began in 1978 when Deng Xiaoping emerged in the internal fight for the succession to Mao Zedong.³ The reform started allowing market incentives in rural areas through the Household Responsibility System. Gradually, this led to a reduction in state intervention, liberalisation of prices, opening up of Special Economic Zones, and dismantling of the commune system. However, a new institution, Township and Village Enterprises, emerged in this period, combining the local government's (top-down) and peasants' (bottom-up) initiatives. Indeed, the role of the state was reallocated from central to local governments, rather than tout-court opposed (Lu, 2000). This phase was also labelled 'reform without losers,' characterised by "the central government strategy of letting the nonstate sector grow without downsizing the state sector" (Zhu, 2012, p. 116), so that the resistance against the reform was minimal. This phase, especially between 1978 and 1984, was characterised by an increase in employees' income share (Molero-Simarro, 2015).

To accelerate reform, Deng carried out a tour in South China in 1992, investigating and promoting the experience of some areas that benefitted most from previous liberalisation (i.e., those benefitting from favourable natural advantages, as shown in Goodman and Segal, 2002). This travel is also recalled for Deng's famous slogan "Let some people get rich first" and for revealing the acceptability of an unbalanced trajectory across provinces as well as a conception of development in which income growth is paramount. In 1993, the 14th National Congress of the Communist Party of China endorsed the creation of a modern enterprise system. This implied restructuring and privatising SOEs under the guiding principle of 'retain the large, release the small': small firms were sold and leased, while the government maintained control over larger, more strategic ones. After Deng's death (1997), Jiang Zemin implemented similar policies, favouring the inflow of foreign direct investment, reforming the banking system, and adopting other policies in favour of privately owned and foreign-invested manufacturing enterprises for the purpose of admitting China to the World Trade Organization.

The neoliberal approach that typified the 1990s was abandoned in the new millennium, leaving room for what Lo (2016a) called the 'Golden Age' model, featuring rapid growth in wages (higher than GDP growth) and in labour productivity (driven by productive investments). This phase is also characterised by new relations with the rest of the world. The 1997–1998 Asian crisis called into question the effectiveness of neoliberal receipts (based on the assumption of capital flows towards poorer countries) and taught China not to implement uncritically the Washington Consensus receipts (Lo, 2016b). The new millennium has also been characterised by a stronger focus on redistribution: in 1999, China launched its 'Western Development' campaign to promote growth in inner backward areas; and in 2005, the new leadership adopted the goal of making China a 'harmonious society' (和谐社会), prioritising issues such as rural development, employment, healthcare and education, environmental protection, the legal system, and social security. The current president Xi Jinping has maintained coherent policies, targeting poverty eradication and the achievement of a 'moderately prosperous' society within his 'Chinese Dream' discourse.

The aforementioned reform approaches involve several aspects of economic activity, living conditions, and beliefs. The healthcare sector is no exception. Before 1978, under the

³ We cannot neglect the importance, for better or worse, of previous policies by Mao Zedong. Deng's reform did not occur in a vacuum; results achieved since 1978 are related to previously implemented infrastructure and human capital investments (Arrighi, 2007; Lu, 2000).

centrally planned system, communes and brigades were the core institutions responsible for the production and distribution of goods and services. Amongst the welfare services provided, theoretically with full population coverage, there was the healthcare sector, efficiently managed thanks to mass mobilisation (in health education and public hygiene) and the guidance of a 'prevention first' principle. These factors, and the work of a system of barefoot doctors, enabled China to achieve remarkable results despite its low level of income (Lu, 2006).

Subsequent reform, especially during the 1993–1999 phase, reversed this condition, shifting attention almost entirely towards economic growth. This strategy did not favour the translation of GDP growth into health conditions (and, more generally, welfare), with lower-than-expected health outcomes, breaking the virtuous circle between economic and human development and eventually leading to unsustainability and population risks (Biggeri, 2007; Duckett, 2007).

Some features of the transition had severe impacts on healthcare. For example, the dismantling of the commune system implied the collapse of public institutions in charge of health services provisions;⁴ the end of the full employment policy (the 'iron-rice bowl') endangered not only jobs but also all workers' social security schemes; the regional imbalance between growth rates implied inequality in the state's capacity to provide healthcare and welfare (Lu, 2006). Duckett (2007) identified 'overlapping patterns of inequality' in access to healthcare services, resulting in discrimination against women, middle-aged men, peasants, and inhabitants of inner provinces. The outcomes of health policies during the first two phases of reform (between 1978 and 1999) appeared in a World Health Organization report (2000), which ranked China 188th in the 'fairness of financial distribution' in its health system.

Another variable that is a testament to the negative influences of reform on China's health sector is life expectancy at birth. Cornia, Rosignoli, and Tiberti (2009) compared the trend of life expectancy before and after 1980, finding that between 1980 and 2000, Chinese people lost 3.6 years on average against a counterfactual scenario based on the continuation of pre-reform policies (despite the positive effect of improved income per capita).⁵ Analogously, Lu (2006) investigated the causes of poor life expectancy improvements and the reappearance of infectious diseases between 1978 and 2002, identifying three main elements: marketisation, privatisation, and adoption of the 'treatment first' approach. The official data on health expenditure shown in Figure 1 support the conclusion about the first two points.⁶

Figure 1 also indicates how, during the latest phase of reform, the state has (re)gained increasing importance consistent with the 'Golden Age' model. In dealing with channels through which the government re-launched its presence, an important aspect has been the reconstruction of insurance schemes to address the deleterious health consequences of dismantling the commune system. In 1998, Urban Employee Basic Medical Insurance (UEBMI) was launched in an attempt to expand the number of beneficiaries of health insurance services within the formally employed urban population. The rural population, excluded from UEBMI, was reached by the New Cooperative Medical Scheme; this

⁴ This choice resulted in an urgent but long-unaddressed problem of a lack of public support in the healthcare sector.

⁵ Among the possible causes of such an impressive reduction, the authors listed income inequality and volatility, psychosocial stress, gender discrimination in education, and declining access to healthcare services.

⁶ The burden of paying for market and private health services led health, along with education and housing, to be one of the 'three big mountains' faced by Chinese people.

programme was introduced in 2003 to cover the rural population on a voluntary basis and constituted a major turning point in Chinese health policies. Finally, Urban Resident Basic Medical Insurance, which was launched in 2007, has further enlarged the number of beneficiaries, including the entire urban population based on residence status. The literature has been quite cautious in describing the positive impacts of such programmes, pointing out their high costs (Yang & Wu, 2014), geographic inequality (Huang, 2015), and limited efficiency (Huang & Gan, 2017). The government, however, is strengthening relevant efforts with the aim of achieving universal health coverage by 2020, which could result in further improvements, especially if the current fragmentation in health institutions and policies is addressed properly (Meng, Fang, Liu, Yuan, & Xu, 2015).

Source: 2016 China Statistical Yearbook.

Figure 1. Private health expenditure in China, 1978–2015.

Finally, it is important to realise that the effects of transition and modernisation throughout the health sector are not limited to the direct effects of health reforms and facilities (Cao, Hansstein, & Liu, 2014) but rather involve various elements related, for better or worse, to Chinese residents' new lifestyles, consumption behaviours (Li, Miao, & Chen, 2015), and productive structure (e.g., industrial pollution and artificial intelligence that can perform medical activities).

HEALTH STATUS OUTCOMES

China has achieved tremendous improvements in population health status throughout past decades, such as increasing life expectancy and reduced mortality. However, these improvements were realised largely during the pre-reform period, with a substantial slowdown in growth since the 1970s. In this section, we aim to contribute to the debate about

China's health status and life expectancy during the reform period by providing a systematic historical and global comparison of China's health status since the 1960s (data prior to 1960 are scarcely available).

Life Expectancy

China's life expectancy increased from 35 years of age in 1949 to 77 years of age in 2018. However, as pointed out in Lu (2006), such success was mostly achieved before the reform; strong growth in life expectancy was lost after the reform began. Dividing China's post-1949 history into two periods, namely pre-1979 (pre-reform) and post-1979, the improvement in life expectancy was much greater before 1979 than afterwards. The first row in Table 1 shows the annual growth in life expectancy between 1960 and 1978 as 1.38%. Annual data on life expectancy between 1949 and 1960 are unavailable. The life expectancy was 35 years in 1949 and 44 in 1960, indicating that a nine-year increase was realised in 11 years. Then, it took only seven years for life expectancy to increase by another nine years. Thus, if the period of 1949–1959 is included, then the pre-1979 growth rate will be marginally lower than 1.38% but still quite high, especially compared with post-1979 growth. This evidence substantiates the argument that China's improvement in life expectancy has substantially underperformed during the reform period.

Although the weak improvement in life expectancy during the reform period is apparent, the aforementioned statement may not hold water. Figure 2 presents the life expectancy of twelve world regions, including China, since 1960. China's growth in life expectancy was rapid during the 1960s but decelerated throughout the 1970s. This visual illustration is supported by time series analyses on the growth rates of China's life expectancy during various periods since 1960. The fifth row of Table 1 shows that, between 1979 and 2017 – namely the entire reform period until the present – life expectancy grew by 0.27% per annum, much lower than the 1.38% during the pre-reform period. However, the decline in growth had already started in the beginning of the 1970s (i.e., before 1979). Therefore, it is safe to say that the substantial pre-reform growth in life expectancy was largely due to the great jump in the 1950s and the 1960s and would never be reached again thereafter (see Table 1 and Figure 2). The year 1970 represents a watershed in life expectancy growth, despite the economic situation during the 1970s being better than that during the 1960s; only 1976 showed negative GDP per capita growth, -3.08%. Another hypothesis about the driver of the decline in life expectancy in the 1970s is the Cultural Revolution, during which China suffered from severe socioeconomic turbulence.

How did life expectancy evolve during different phases of the reform? The last three rows of Table 1 reveal no qualitative differences in growth of life expectancy throughout the reform; growth rates for the initial phase, neoliberal phase, and 'Golden Age' phase are 0.26, 0.28, and 0.24. The neoliberal period demonstrated even higher growth, despite such a marginally higher rate potentially not having economic significance (we will return to this point in our econometric analysis of mortality).

Has China's performance during the reform fallen behind that of other world regions? As Figure 2 shows, the jump in the 1950s and 1960s led China's life expectancy to exceed other developing regions since the 1970s, second to only traditional developed countries and

transition countries (until the early 1990s). Since the 1980s, China’s life expectancy has even surpassed that of Russia and less advanced transition countries. Since the 2000s, China’s life expectancy has remained nearly the same as that of advanced transition countries, only second to traditional developed countries. Therefore, despite the slowdown in life expectancy improvements during transition, China has continuously moved upward in the global hierarchy of life expectancy.

Table 1. Growth rate of life expectancy in China since 1960

Period	Growth Rate	Adj. R ²	Life Expectancy Range
1960–1979 (pre-reform)	1.38***	0.97	43.7–65.9 (1.23 per annum)
1970–1990 (post-1960s–Reform 1)	0.48***	0.91	59–62.3 (0.52 per annum)
1970–2000 (post-1960s–Reforms 1 & 2)	0.35***	0.9	59–72 (0.43 per annum)
1970–2017 (post-1960s)	0.32***	0.98	59–76.4 (0.47 per annum)
1979–2017 (Reforms 1, 2, & 3)	0.27***	0.99	66.4–76.4 (0.26 per annum)
1979–1990 (Reform 1)	0.26***	0.96	66.4–69.3 (0.26 per annum)
1991–2000 (Reform 2)	0.29***	0.66	69.4–72 (0.29 per annum)
2001–2017 (Reform 3)	0.24***	0.96	72.4–76.4 (0.25 per annum)

Note: Growth rate (r) is estimated by the following trend equation: $\ln(\text{Life Expectancy}) = a + rt + u$. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$. Reforms 1, 2, & 3 refer to the three distinct phases of China’s reform (exploratory phase, neoliberal phase, and ‘Golden Age’ model, respectively).

Source: World Development Indicators.

Figure 2. Life expectancy: A global comparison.

Visual inspection does not indicate that China's life expectancy growth has significantly lagged behind other developing regions since 1979. The time series analysis in Table 2 shows that the annual growth rate of life expectancy in China since 1979 is comparable to middle-income countries (0.28%), Latin America and the Caribbean (LAC), and Sub-Saharan Africa (SSA) but lower than low-income countries, those in the Middle East and North Africa (MENA), and South Asia. Traditional developed countries and transition countries exhibit the lowest growth. Except for Sub-Saharan Africa, growth in life expectancy appears to decline with income; China's performance is consistent with this trend. Moreover, China's absolute level of life expectancy is higher than the average level of countries with a similar income level. Given that the growth in life expectancy has a decreasing margin, China's growth performance may be better than the average performance of countries with a similar income level. Between 1979 and 2000, Russia experienced declining life expectancy, and Central Europe and the Baltics had much lower growth rates, whereas MENA and LAC countries showed more rapid growth in this period (which has slowed since 1990 and since 2000). Considering the decreasing margin of life expectancy of MENA and LAC, China has not underperformed with respect to other developing countries; rather, the difference compared with other transition economies favours China and is remarkable.

Table 2. Life expectancy growth since 1978: A global comparison

World Region	1979–2017	1979–2000	1990–2017	2000–2017

Middle East & North Africa	0.41*** (57.5)	0.62***	0.26*** (66.1)	0.23*** (69.3)
South Asia	0.42*** (53.5)	0.45***	0.4*** (58.2)	0.37*** (62.9)
Sub-Saharan Africa	0.32*** (47.9)	0.09***	0.48*** (49.9)	0.65*** (50.5)

Note: Growth rate (r) is estimated by the following trend equation: $\ln(\text{Life Expectancy}) = a + rt + u$.

*** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$. Life expectancy at birth in the starting year is given in brackets.

Mortality

Mortality in China since the 1960s shows a pattern consistent with life expectancy; although China witnessed a great improvement in the 1960s, the improvement has been quite modest (if any) since the late 1970s. As Figure 3 shows, in the first two years of the 1960s, the death rate per 1,000 people declined suddenly from almost 26 to only 10. Then, except for 1964, the death rate fell continuously until the late 1970s. On the contrary, the early years of

the reform showed a slight increase in mortality that remained thereafter at around 6.5–7 until another increase in the late 2000s. The slight increase in most recent years is likely due to aging. To account for this effect, as well as the role of other covariates, we have run a panel regression (see *infra*).

China's reduction in mortality before reforms has stood out in a global comparison. Between the late 1960s and early 1990s, China's mortality was lower than all other world regions (excluding developing countries in East and Southeast Asia). Since the early 1990s, LAC and MENA countries have had lower mortality than China; however, this may be due to the younger age structure in these countries (since the early 1970s, the LAC's and, especially, MENA's population share aged 65 and above has been significantly lower than that of China). Similarly, China's high proportion of a young population in the 1960s and 1970s may elucidate its low mortality during those decades. Therefore, the already lowest mortality in the world and increasing aging can both explain stable mortality during the reform period. By contrast, Russia and less advanced transition countries (former Soviet Republics and Albania) showed a modest increase in mortality between the early 1960s and early 1990s and a sudden, huge increase since then, consistent with the hypothesis of the detrimental effect of transition on health.

Source: Authors' own calculation based on WDI data.

Figure 3. Mortality: A global comparison

Figures 4 and 5 display the evolution of mortality in 31 provinces from 1990 to 2016, indicating strong cross-provincial variance in the results. The three provinces in Southwest China (Sichuan, Guizhou, and Yunnan), three provinces in Central China (Jiangxi, Hubei, and Hunan), and four autonomous regions (Inner Mongolia, Guangxi, Tibet, and Xinjiang) had the highest mortality in the 1990s. All autonomous regions have demonstrated significantly reduced mortality and the lowest mortality since the 2000s, whereas Southwest China, despite a reduction, still exhibits higher mortality than other regions. North China, Northwest China,

and Central China have each had less change in mortality than other regions. Surprisingly, Northeast China had very low mortality between the mid-1990s and late 2000s (except Liaoning in the late 1990s). This region is notorious for restructuring, inefficient SOEs, and great waves of layoffs, all of which are associated with high levels of stress. Guangdong, another province with one of the greatest degrees of restructuring, has also had lower mortality than most other provinces; indeed, it has had one of the lowest mortality rates amongst all provinces since the 2010s. Guangdong and Northeast China represent two polar examples of restructuring: in the former, restructuring has been associated with emerging opportunities and higher labour intensity (even sweatshops); in the latter, restructuring has been tied to decreasing opportunities and shrinking employment. According to Biggeri (2003), North China, Central China, Northwest China, and Southwest China appear less dynamic, with a lower degree of restructuring and marketisation; their mortality trends are heterogeneous (stagnant in North China, slight declines in Northwest and Central China, and a substantial decline in Southwest China).⁷ At any rate, the geographical pattern of mortality across provinces does not show a clear relationship between restructuring (and thus stress) and mortality.

Source: China Health Statistical Yearbook (various years).

Figure 4. Mortality at the regional level.

⁷ Jiangsu and Zhejiang also had very little change, but these provinces already had a much lower share of state-owned enterprises in terms of total industrial output compared with other provinces in 1986. Mortality in autonomous regions may be unique, as these regions tend to have a severe natural environment (e.g., Tibet and part of Inner Mongolia and Xinjiang) and receive special policy.

Mortality may be attributable to various factors, amongst which stress due to socioeconomic restructuring can emerge as a critical phenomenon during transition phases (Cornia, 2016). For large transition countries (e.g., Russia and China), different regions may experience distinct levels of socioeconomic restructuring. Popov (2011) found that, in Russia, regions with higher real income growth and higher labour turnover, which indicate faster restructuring, have higher mortality. Moreover, regions with more economic opportunities (e.g., resources) and thus greater economic restructuring and stress, such as the North (Arkhangelsk and Komi), Siberia and Far East (Tyumen and Kamchatka), and Moscow, tend to have lower life expectancy than regions with fewer economic opportunities and thus less restructuring and (at least economically related) stress, such as North Caucasus (Ingush, Dagestan, and Kabardino-Balkar).⁸

Source: China Health Statistics Yearbook (various years).

Figure 5. Mortality at the regional level (Cont'd).

How can cross-regional variation in mortality in China be explained? Did the neoliberal 1990s negatively influence mortality? We have implemented a fixed-effects panel regression on province-level mortality with respect to socioeconomic factors for 31 provinces in the Chinese mainland from 1990 to 2016. Variables of interest include age structure (the share of population aged 65 and above), development level (GDP per capita; beds and doctors per 10,000 people), growth (GDP per capita growth rate), economic restructuring (unemployment; the ratio of employees in the urban public sector and formal private business

⁸ It should be noted that North Caucasus has a unique culture and lifestyle (e.g., stronger family ties) that may influence the local population's response to restructuring and change.

to total urban employment), neoliberal reform (time dummy for the 1990s), divorce rate (available from 1999), urban–rural disparity (the ratio of urban income to rural income), and year trend. In China, public-sector employees, including some (i.e., those with permanent employment) in state-owned and collective enterprises, receive exclusive state-provided welfare and security, especially healthcare. Those working for large private companies and multinational enterprises have higher and more stable salaries and are more likely to have better access to public services. Conversely, employees working in small private enterprises and those who are self-employed tend not to be covered by formal welfare and security and must cope with problems, risks, and uncertainties using their own (typically limited) resources. This population group is more likely to suffer from stress. The ratio of those who are ‘institutionally protected’ by the state or by ‘money’ to those who are ‘unprotected’ measures the share of people without (much) stress and with security. As pointed out by Graham, Zhou, and Zhang (2017), the lack of security during China’s reform has been a major source of life dissatisfaction. A reduction in this ratio may be driven by two factors: a reduction in the numerator and an increase in the denominator. The first case indicates the laying off of employees from the ‘protected’ sector, resulting in higher levels of stress. The second case may indicate the growth of the urban labour force in the private sector due to peasant immigration from rural areas or shrinking inactive and unemployed population segments. The second case therefore has a more ambiguous association with stress.

Table 3 presents the results of panel regressions. Because GDP per capita, doctors per 10,000 people, and beds per 10,000 people are highly correlated (i.e., correlation coefficients greater than 0.6), they are used separately in different specifications to control for the effect of development level. Urbanisation is often used as a control variable in the mortality literature, but it could not be controlled over our sample because its measurement is subject to inconsistency before and after 1998.⁹ The exclusion of urbanisation should not be a problem, as it is closely correlated with GDP per capita and beds and doctors per 10,000 people.

Aging significantly increases mortality. A one-standard-deviation increase in aging increases mortality by around 0.44‰ across the four specifications. GDP per capita is not statistically significant, while a one-standard-deviation increase in doctors and beds per 10,000 people increases mortality by 0.26‰ and 0.22‰. The finding that more sufficient healthcare facilities increase mortality seems counterintuitive, despite the actual effect being relatively small. However, Popov (2011) similarly found a slightly negative impact of beds per capita on life expectancy in Russia. He suggested that the collapse of the free healthcare system in the post-Soviet period caused the poor to be unable to afford health facilities and that only relatively rich people could take advantage of improved health facilities. Lu (2006) argued that the retreat of the state from healthcare, the shift from prevention to treatment, and the overall marketisation of healthcare have shifted healthcare services to a profit-making orientation and, in many cases, improvements in health facilities have exceeded the affordability of ordinary people. In this sense, our finding lends support to the argument that healthcare marketisation during the transition period is not friendly to the poorer population in China, as with the case of Russia.

⁹ Data on province-level urbanisation from 1990 to 2008 are from the China Compendium of Statistics 1949–2008; data for the period of 1998 to 2018 are from the China Statistical Yearbook (the pre-1999 Yearbook was not available to us). The two datasets have significant discrepancies.

GDP percapita growth slightly reduces mortality in the first two specifications (a one-standard-deviation increase reduces mortality by 0.038). Unemployment is not statistically significant. Notably, our data on unemployment are from the China Statistical Yearbook, and the reliability of China's official unemployment data has often been doubted.¹⁰ The public ratio significantly increases mortality in two out of three specifications. The impact of a one-standard-deviation increase is 0.3. This result seems to counter the hypothesis that higher shares of employees in 'institutionally protected' sectors lead to better overall health status. Time series analysis reveals that the public ratio exhibits significant downward trends for all 31 provinces, and mortality shows decreasing trends in all but three provinces since 1990 (results are available upon request). A declining public ratio implies growth in the urban private sector and transformation of the rural labour force into an urban labour force. This process is driven by economic growth and stimulates further economic growth, which leads to higher living standards and more resources and capacities related to healthcare (that was no longer freely available from pre-reform public institutions). Moreover, peasants' immigration from the countryside to urban areas, namely the transformation from peasants to (peasant) workers, has increased the material living standards of this population segment (through higher wages and a better living environment). Since the early 2000s, the state has played an increasing role in public healthcare, and social security and health insurance have been established and strengthened. These factors are expected to reduce the healthcare differential between the 'institutionally protected' sector and 'unprotected' sector. In this sense, economic development and positive institutional change (e.g., the proactive establishment and expansion of social security) may have compensated for or even reversed the otherwise 'painful' transition from 'institutionally protected' to 'unprotected' firms. Provinces with a more dynamic private sector generally succeed in collecting more resources to enforce inclusive social services, given the highly decentralised financial regime established by Beijing (Shue & Wong, 2007). These empirical findings suggest that such provinces tend to have lower mortality, thereby compensating for the adverse effects of privatisation.

Table 4 presents the results after including divorce rate, another indicator used in the transition literature to proxy the extent of social and individual stress. Divorce data were only available from 1999, reducing our sample size. Consistent with findings from other transition countries, divorce significantly increases mortality in all specifications, suggesting stress as an important contributor to mortality in China. Moreover, in this context (a country with Confucian traditions and strict control over citizens' personal lives during Mao's era), divorces can be a proxy for shifting social norms around relationships and marriage.

Overall population mortality may be ascribed to many factors, some of which are not directly related to health facilities or healthcare input; rather, maternal and early-childhood mortality directly reflects the sufficiency and quality of health facilities and personnel. Similar to life expectancy and overall mortality, China has tended to outperform other developing regions in maternal and early-childhood mortality. Figure 6 shows that, in the early 1990s, China's maternal mortality was already lower than in other developing regions – particularly compared to that of middle-income countries – and was close to the level of Russia and less advanced transition countries. Over the past three decades, maternal mortality in less advanced transition countries, including China, has continued to approach that of

¹⁰ See, for example, Athukorala et al. (2009). The highest unemployment rate in our database is only 7.4%; a clearer picture of unemployment can be provided by micro-level analysis (see *infra*).

traditional developed countries and advanced transition countries. No significant difference has emerged between the two groups since the early 2010s. China's reduction in maternal mortality is highly linear without significant differences across the three phases of reform.

Figure 6. Maternal mortality: A global comparison.

Other indicators that offer insight into the association between transition and health status are the top causes of death. What are the major causes of mortality in China? How have they changed over the past decades? Tables 5 and 6 list the top five reasons for death in China's urban and rural areas, which exhibit different rankings. Death by cause has remained highly stable in urban areas, but some significant changes have occurred in rural areas. Respiratory diseases ranked first on the list of death by cause until 2005 but fell to 4th place in 2010 and 2015. Malignant neoplasms, cerebrovascular diseases, and heart disease have emerged as the top three causes of death. Because the morbidity of respiratory diseases is closely related to healthcare and health facilities, its declining rank may indicate improving health conditions across China's rural areas. Conversely, the rise in malignant neoplasms, cerebrovascular diseases, and heart disease may imply that, like their urban counterparts, the rural population has increasingly suffered from stress and an unhealthy lifestyle, presumably as a socioeconomic effect of transition.

Mortality and Health Status amongst Chinese Individuals

Micro-level data provide another perspective on the evolution of mortality and health status in China. This type of analysis is less suited to delineating the structural transformation of society as a whole, but it can reveal how different individuals react to such changes over time. Several datasets are available to analyse the socioeconomic characteristics of Chinese households. Amongst these, we refer to data from the China Health and Nutrition Survey (CHNS); this dataset is provided by the Carolina Population Center at the University of North Carolina at Chapel Hill and the National Institute for Nutrition and Health at the Chinese Center for Disease Control and Prevention. The CHNS is widely appreciated in the literature owing to its focus on health, having collected panel data over a relatively long time: the first wave of information dates back to 1989 (before the neoliberal phase); the latest wave, the tenth, occurred in 2015. The CHNS sample is selected through a multistage random cluster process, resulting in a sample of about 30,000 individuals in twelve (out of 31) Chinese provinces in the eastern, central, and western regions of the country.

Besides data regarding objective and self-reported health status, CHNS questionnaires collect information about each sample's socioeconomic characteristics. Our analysis considers variables such as educational attainment, employment, and income to observe how the health status of different social groups has been affected by the Chinese transition. Whilst life expectancy can only be computed over an aggregated sample, we can focus at the individual level on age at death (see also Chapter 5). This variable can be computed only amongst the subsample of individuals who were alive during the initial waves of CHNS and died before 2015 (the year for which data are most recently available). This subsample includes 2,302 observations and shrinks to 2,255 when only adults are considered.¹¹ We computed pairwise correlations to investigate which socioeconomic characteristics contribute to higher (or lower) ages at death; see Table 7. Positive correlations indicate longer lifetimes and are therefore considered positive factors. Our regression analysis was less informative, as the sample size (already reduced due to excluding surviving individuals) was further reduced by sensitive questions that were not asked in every wave or for which missing values were

¹¹ The exclusion of non-adult individuals from the sample is necessary to allow for comparability across observations (variables such as smoking habits or employment conditions are distributed differently amongst non-adults) and to discard cases of infant mortality related to causes that were not massively affected by transition (Chapter 4).

frequently reported. However, the significance level of most correlations indicates that the results are robust, and their interpretations appear consistent with our expectations.

The variable showing a stronger negative correlation with age at death (i.e., the variable that reduces longevity most) is unemployment. Smoking and alcohol behaviours and belonging to an ethnic minority also significantly reduce the age at death.¹² Women have died later on average. Household income per capita and geographical residence also seem to affect longevity. Other significant positive correlations include belonging to coastal provinces (i.e., the area that has benefitted most from reforms as evidenced by higher economic growth and modernisation) or to urban areas and having an urban hukou.

Table 7. Correlation between individual characteristics and age at death

Negative Correlation		Positive Correlation	
Unemployed	-0.17***	Female	0.15***
Ever Smoked	-0.09***	Lives in Coast Area	0.11***
Ethnic Minority	-0.09***	Urban hukou	0.10***
Alcohol consumption	-0.04*	Lives in Urban Area	0.09***
		Income per capita	0.05**

Source: Authors' own calculation based on CHNS.

The hukou, or household registration, is a system of domestic passport introduced in China in the Maoist period. The hukou identifies each citizen's official residence area; more importantly, given the close association between official residence and the welfare system, the hukou identifies the administration responsible for providing healthcare, education, and other social security services. This institution gained relevance with market reform beginning in 1978 because the dismantling of the commune system and the growing importance of market mechanisms in the labour market compelled many people – especially rural peasants – to move from their hometowns to areas with more or better-paying jobs. Domestic migration driven by reform thus implied a separation between the official hukou and the actual places where individuals live and work. The government partially relaxed the hukou system thereafter, of which the 2014 reform is arguably the most notable example. However, domestic migrants' and locally born workers' access to welfare services still constitutes a major form of discrimination (Pi & Zhang, 2016; Zhang, Wang, & Lu, 2019).

Returning to the longevity analysis, the hukou system remains a crucial element, as the advantages bestowed upon individuals with an urban hukou even exceed those granted to individuals effectively residing in urban areas. Therefore, rural people's migration to urban areas appears insufficient in closing the gap between urban and rural life expectancy without the government further addressing the complete integration of domestic migrants into recipient areas.

The aforementioned factors are also intercorrelated. For example, drinking and smoking are strongly related and are each significantly correlated with unemployment status. Even so, smoking and drinking do not overlap geographically: smoking is more widespread in poorer regions (rural and inner areas), whereas alcohol consumption demonstrates the opposite pattern.

¹² These are binary variables, referring respectively to reporting a frequency of alcohol consumption equal to or greater than three times per week and to ever smoking a cigarette or pipe.

Another way to explore health status through micro-level data is by investigating the determinants of health problems and unhealthy behaviours (e.g., smoking and drinking, whose longevity-related effects were just discussed). To perform such an analysis, we can broaden the sample to all surveyed individuals, obtaining a sample of 99,106 adults (the final sample was slightly smaller due to missing information). We consider the following five indicators of health problems, including objective and subjective measures: undernutrition, obesity, high blood pressure (HBP), dissatisfaction, and sickness. These indicators are all binary variables, where 1 corresponds to the presence of a given health problem and 0 otherwise; this similarity favours the comparability of regression analysis across different specifications of health problems and unhealthy behaviours. Undernutrition, obesity, and HBP are identified by the standard thresholds (respectively a body mass index below 18.5; body mass index above 30; and systolic pressure above 140 and diastolic pressure above 90). Dissatisfaction corresponds to individuals who answered ‘poor’ in response to the question “Right now, how would you describe your health compared to that of other people your age?”; this variable was recorded in only three survey waves (1991, 1993, and 1997), leading to a much smaller sample size for this analysis. Sickness corresponds to individuals who reported having been sick or injured within four weeks before the interview.

Table 8 reports the coefficients of probit regressions that explain these eight binary variables for health status with socioeconomic characteristics: age; the number of years under study; belonging to an ethnic minority (0 = Han majority, 1 = any other ethnic group); gender; living in an urban area and possessing an urban hukou (the interaction between living in an urban area and having a rural hukou is named ‘irregular’ and captures the effect of domestic migrants living in an urban area without being able to fully enjoy the rights of urban-born citizens); employment status; household income per capita; and living in a coastal province. Finally, trend coefficients are computed based on the observation year.

These regressions provide new insight into the channels through which Chinese individuals’ health conditions are (unequally) affected. It is important to note that all variables of interest, whether self-reported or based on objective indicators, are positively correlated with health problems: negative coefficients indicate a healthy status and vice versa.

As expected, age represents one factor exerting the most significant negative impact on health. Further analyses, which are not reported due to space limitations, reveal age to exhibit a non-linear inverted U-shaped trend. Another element correlated with general worsening of health status is unemployment. The negative effect of unemployment, which was not fully captured with macro-level data, emerges clearly at the micro level, affecting self-reported and objective indicators.

Another factor whose coefficient maintains its sign irrespective of the health specification is education, which remains positive for all health conditions. Similarly, income is generally positive, the most notable exception being a higher risk of becoming obese. Ethnicity, gender, and geographical residence (effective and official) have contrasting effects; for example, more advanced areas (i.e., coastal and urban) report lower cases of undernutrition, but obesity is more common, and people report more frequent sickness (this pattern may also be attributable to greater awareness of such problems).

The exogenous trend characterising these indicators is also mixed. While negative behaviours generally decline, the number of individuals experiencing HBP or reporting cases of sickness increases; the shrinking of undernutrition cases is counterbalanced by the emergence of an obesity problem.

Source: Authors' own calculation based on CHNS.

Another variable in the CHNS is ownership of medical insurance. Although this information reflects the healthcare system rather than health outcomes, it is interesting to consider how the variable correlates with socioeconomic characteristics. An econometric regression (results available upon request) shows that, *ceteris paribus*, people with insurance are significantly richer, more educated, older, and live in urban and coastal areas. By contrast, migrants without the urban hukou and ethnic minorities possess significantly less insurance coverage. The trend in this healthcare variable is, as expected, significantly positive; the greatest improvements in health insurance diffusion occurred in the new millennium, consistent with the 'Golden Age' model. In other words, analysis of health insurance indicates that the most vulnerable social groups are also those who generally encounter discrimination in health insurance access, underscoring the importance of the inequality issue from a healthcare perspective (even though the government's recent efforts to rebalance the transition have proven effective).

WHAT MAKES CHINA UNIQUE?

Although China's health performance during the transition (especially in the neoliberal phase) has been weaker than before, a comparison with other transition economies reveals clear differences. In contrast to countries that followed the Washington Consensus, Chinese life expectancy has grown during the transition period, and economic restructuring has contributed to lower mortality. This anomalous case of transition presents interesting questions. Domestically, how could China maintain such stable growth in life expectancy – even in the neoliberal period – despite a rather regressive healthcare policy regime? Globally, why has China maintained stable improvements in life expectancy in the absence of a downturn or stagnation (despite slower growth than in the 1960s) compared with other transition countries, especially the former Soviet Republics?

China's stronger performance in life expectancy can likely be ascribed to a gradualist reform strategy (in contrast to 'shock therapy') and strong institutions (i.e., the state's strong control over its economy and society under the Communist Party regime, despite marketisation). A gradualist approach towards marketisation, to some extent, saves the economy from great unemployment, bankruptcy, and loss of labour rights after privatisation. Moreover, when these detrimental phenomena occur, they are arguably less unexpected and unattended, limiting their effects in terms of stress-related mortality. Strong institutions control a range of social problems related to socioeconomic liberalisation from the previous highly planned and regulated regime, particularly violent crime. Moreover, these institutions can be (perceived as) elements that prevent further deterioration of quality of life (further analysis on the roles of institutions in addressing stress-related mortality are provided in Chapter 2). As a result, under a relatively stable, less uncertain, and less volatile transition, China has managed to maintain an improvement in life expectancy.

China's transition, attacked by supporters of the Washington Consensus for being too smooth and incomplete, appears to be a rather effective strategy for preventing individual and social stress. By contrast, shock therapy and a sudden transition to (de jure) democracy led to uncertainty and volatility in other transition countries that lack a strong democratic tradition and good institutions, especially the former Soviet Republics. A direct consequence is strong stress amongst the population, especially fragile segments, and an accompanying deterioration in life expectancy.

Moreover, China's case may not be explained by the gradualist approach and strong institutions alone; the unique nature of Chinese capitalism underlying the nation's strong economic growth is another possible contributor to its better health performance. A major difference between China and other transition countries is that, as a late industrialiser, China's priority during the economic reform is to develop its economy through industrialisation. Conversely, other transition countries in Central and Eastern Europe had already achieved industrialisation by the 1940s, meaning that they were already developed countries in absolute terms. For these countries, transition is more driven by the goal of transforming a centrally planned political and economic system into liberal capitalism, whereas China's transition has a clear dual goal of not only reforming the political and economic system but also achieving economic growth. This latter aspect has led the Chinese state to become a developmental state, which corresponds to the cases of South Korea and Taiwan during their

economic catch-up.¹³ The Chinese state as a developmental state has been a core driver of strong growth since 1979, which thus enhanced, along with strong institutions, the stable improvement in life expectancy and mortality reduction.

China's Competition-Driven Local Developmental State

In this section, we introduce the 'Varieties of Capitalism' (VoC)/'Comparative Capitalism' approach from comparative political economy to provide new insight into the influence of China's political economy on health status in addition to its gradualist strategy and strong institutions. China's reform since 1978 represents an inherent transition from a typical centrally planned economy to a unique type of capitalism. The three distinct phases of reform reflect a process of exploration and adjustment. In the 1980s, the state cautiously launched marketisation, and economic growth emerged as the top goal. The 1990s witnessed radical marketisation in the spirit of neoliberal economic ideology and the permeation of market principles into most socioeconomic spheres. Economic growth then became the government's top priority to the neglect of social development and the environment. Since the 2000s, although economic growth has remained a priority amongst the central and local governments, distribution, welfare, and sustainability have been explicitly placed on the policy and development agenda, especially at the central level. The China-specific competition-driven local developmental state is a variant of both state-permeated capitalism and the developmental state formed during these three phases of reform. China's structure of multilevel governance and the relatively great autonomy of the local government are also crucial to understanding the impact of political economy on healthcare from a local perspective.

The VoC approach is dominant in research on the institutional arrangement of contemporary capitalism and China's capitalism (Ahrens & Jünemann, 2010; Andreosso-O'Callaghan & Gottwald, 2014; Witt, 2010). In their landmark book *Varieties of Capitalism: The Institutional Foundations of Comparative Advantage*, Hall and Soskice (2001) conceptualised the institutional arrangement of the capitalist system in developed countries and identified two distinct types of market economies, namely liberal market economies, represented by the United States and the United Kingdom, and coordinated market economies, such as Germany and Japan. These models are distinct in their firm coordination, corporate governance, labour relations, role of the financial sector, and vocational training. In recent years, as a result of the development of the market economy outside traditional core countries (e.g., Western Europe, North America, Oceania, and East Asia apart from China), the original VoC classification has been extended to accommodate new types of capitalist systems: dependent market economies in Central and Eastern Europe (Nölke & Vliegenthart, 2009); and state-led/influenced market economies/SMEs in emerging countries (Schmidt, 2009).

¹³ We must point out that a gradualist strategy and developmental state are non-overlapping elements. China's developmental state originates from the experience of Asian Tigers' state-led capitalism, industrial strategy, and industrialisation; this is unrelated to a gradualist transition. However, both share a strong role of the state in the economy, which counters neoliberal ideology. The developmental state opposes 'shock therapy' in terms of the role of the state but not directly in terms of the pace of reform.

The ‘influencing’ state is the feature that distinguishes SMEs from other regimes (Hall & Soskice, 2001; Schmidt, 2007, 2009; Streeck, 1997). China is undoubtedly classified as an SME. Based on the observation that the state always assumes a pro-business and pro-development role in the national economy in large emerging countries, ten Brink (2013) dubbed the capitalist system in large emerging countries ‘state-permeated market economies.’ The replacement of ‘state-led/influenced’ with ‘state-permeated’ has occurred because, in large emerging countries, the state does not have an ‘all-powerful, centralised, steering’ role or status as conceptualised in the classical developmental state theory inspired by South Korea’s experience (Nölke, ten Brink, Claar, & May, 2015). Instead, the role of the state is realised through state-business coalitions at the central and local levels, which form a fragmented but permeating state presence; that is, the government at each administrative level serves as a local developmental state responsible for local development. Fragmentation and permeation lead to a model of a competition-driven local developmental state. Insiders in state-business coalitions (e.g., a coalition between the provincial government and local businesses) share common interests and goals. Typically, a developmentally oriented government needs to stimulate local economic growth and businesses need to increase profits, meaning that their interests overlap and their coalition is based on reciprocal loyalty and trust (Nölke et al., 2015). Coalitions compete with each other (e.g., between provinces or prefectures) for economic opportunities such as investments. Such coalitions started to develop under rapid marketisation in the 1990s, during which the previous strategy of ‘wearing a red hat’ (de jure state-owned but de facto private enterprises) shifted to formal privatisation, but the state-business coalition was strengthened (ten Brink, 2011).

Source: China Health Statistical yearbook (various years).

Figure 7. Structure of health expenditure.

In many cases, local state-business coalitions compete for economic opportunities at the expense of labour welfare and sustainability. This was particularly the case in the 1990s,

which witnessed a kind of ‘growth fetishism.’ In conjunction with a reserve of cheap labour, this competition has preserved China’s low-wage regime through the intentional absence of intervention in business misconduct, selective implementation of labour laws, decentralisation of regulation of employment at the firm level, and a lack of collective bargaining (ten Brink, 2016). In addition to relatively high labour skills and productivity, the combination of ‘liberal’ industrial relations and low labour costs has served to attract multinational enterprises. The central government’s political approach and competition between local state-business coalitions has placed further downward pressure on labour welfare.

Since the 2000s, China has gradually diverged from the neoliberal doctrine, approaching the ‘Golden Age’ model. The central government has proposed an economic rebalancing, with a shift from investment- and export-led growth to consumption- and service-led growth. This rebalancing implies increasing demand and income, especially amongst poorer segments of the population. Figure 7 displays the three pillars of China’s total health expenditure since 1978. Since the early 1990s, social and governmental health expenditure has followed similar trends, reaching a low point around 2000 and then rebounding during the ‘Golden Age’ period.

Despite its positive role in stimulating economic growth and capital accumulation in the 1990s and 2000s, China’s competition-driven local developmental state, which is embedded in a multilevel governance structure, has weakened the superior government’s control over the inferior government and hindered the central government’s policy and strategy implementation. Beijing’s relatively weak influence has thus hampered the promotion of rebalancing. In this sense, as pointed out by ten Brink (2013), China has produced its own structural and institutional obstacles to economic rebalancing and social upgrading.

Competition-Driven Local Developmental State and Health Status

The implications of China’s competition-driven local developmental state for health status may be complex. Competition between local state-business coalitions suppresses a return to and welfare of labour and increases labour intensity, leading to relatively unfavourable working and living conditions and greater stress. Meanwhile, growth fetishism, embedded in the ‘mindset’ of governments, squeezes healthcare’s position in the policy agenda, reflected in declining governmental contributions to health expenditure. The relatively loose central–local relation also tempers the promotion of rebalancing towards a more pro-poor/labour growth pattern, weakening the positive effect of the transition from neoliberal reform to the ‘Golden Age’ model.

The competition-driven local developmental state may provide additional insight into the retreat of the state, at the central and local levels, from healthcare. As shown in Section 3, in all provinces, governmental contributions to healthcare bottomed out in the late 1990s and early 2000s. The root of this retreat lies in marketisation reform and the state’s shifting role in the economy and politics. If the transition leads to a healthcare recession, which is an unavoidable outcome of marketisation, then competition for economic opportunities, a China-specific factor, may strengthen the negative outcome of the retreat.

At least until the recent decade, the central and local governments had each stimulated economic growth and industrialisation at the expense of population welfare. At the

international level, China preserved its low-wage regime to compete with other low-cost countries for investment. Domestically, as suggested above, local state-business coalitions compete with each other to attract investments in their own territories. The state benefits from such a labour regime through economic growth and industrial development, and businesses benefit from this regime through profit generation. In theory, the state's retreat from healthcare must be compensated by the development of a high-welfare labour regime as an institutional complementarity; however, the competition-led low-wage regime also leads to a vicious complementarity.

Has the central government's relatively loose control over local government dampened the shift in the growth model from neoliberal reform to a 'Golden Age' model or impeded socioeconomic rebalancing? This supposition may not be directly verifiable, but the increasing share of health expenditure to total governmental expenditure in all provinces since the mid-2000s suggests that the local state has positively altered its role in healthcare. This change is consistent with the strategy of socioeconomic rebalancing set by the central government. However, another possibility is that reversal of the previous growth model is a natural reaction to economic growth and capital accumulation. The space and need for further growth and accumulation are likely to follow a declining margin or an inverse U-shaped pattern. After a certain point, a growth model based on low-wage regime will inhibit further growth. When growth and accumulation have reached a certain level, the government will naturally move to a more pro-poor and high-welfare policy regime, either due to the need to shift its growth pattern or in response to public pressure. As suggested in our discussion of health status outcomes, substantial expansion of the resources and technology available for healthcare may compensate for the side effect of the transition and a competition-driven local developmental state. If this pattern holds, then the competition-driven local developmental state has produced its own stimulator of change through its growth-enhancing effect. In this sense, China is a special case compared with other transition countries, at least Russia and those less advanced nations that experience socioeconomic turbulence. Essentially, the key to compensating for the dark side of transition is robust economic growth backed by strong institutions and a developmental state.

CONCLUSION

The transition from a centrally planned economy to a market economy that took place in the 1980s and 1990s across the land between the Oder and the Bering Strait fundamentally changed the politics, economy, and society of those (former) socialist countries.¹⁴ This transition led to severe socioeconomic turbulence and psychological stress in Russia and other former Soviet Republics. The population's health status experienced a great recession in the 1990s and did not return to its pre-transition level until the early 2000s. On the contrary, China has followed a gradualist approach, driven by strong institutions that refused ideological implementation of the Washington Consensus agenda. China has effectively avoided major socioeconomic turbulence and experienced robust and rapid economic growth over the past four decades of reforms.

¹⁴ The transition of the former German Democratic Republic is unique; thus, we use the Oder (the German–Polish border) as the west boundary of the transition.

In this chapter, we have considered China's health achievements during three distinct phases of reform, namely the exploratory transition to a market economy (the 1980s), neoliberal reform (the 1990s), and the adoption of a 'Golden Age' model (since the 2000s), to compare health outcomes amongst provinces, households, and other countries. The growth rate in life expectancy has declined with respect to pre-reform achievements realised in the 1960s. Moreover, health outcomes have been affected by unemployment, inequalities in the distribution of income and education, unhealthy behaviours, and a growing divorce rate. Amongst the major causes of death, the relative importance of stress-related diseases has increased as well. All these factors are consistent with the literature regarding stress and mortality in transition economies. Yet China's achievements in life expectancy have not underperformed in comparison with most other countries, especially transition economies who experienced a 'shock therapy' transition. Indeed, China's improvement in health status has remained quite stable since 1979 despite a regressive healthcare regime and economic restructuring between the late 1980s and early 2000s (i.e., the neoliberal phase, characterised by a higher mortality rate): China did not experience any major downturns even in this phase.

Different from other cases of transition, Chinese provinces with a more active private sector recorded better health outcomes. This pattern may be due to the growth-enhancing effect of China's model of a developmental state. Similarly, inequality between rural and urban areas characterises health outcomes under the hukou system (i.e., China's internal passport) that discriminates against domestic migrants in access to healthcare and in some – but not all – health-related indicators.

In other words, China's transition has led to heterogeneous outcomes, but the country is not underperforming and appears healthier than other transition economies on average. The latest phase of the reform, since the turn of the century, has featured more resources and a greater willingness to invest in the welfare sector, thereby rebalancing economic development towards consumption-led growth. The 2003 health reform was a major policy in this direction.

To conclude, we suggest that robust economic growth and the underlying developmental state, along with gradualist reform and strong institutions, have been key in avoiding a health status recession during the reform: a pragmatic approach to transition can thus elicit more favourable outcomes in terms of human lives with respect to the uncritical adoption of 'shock therapy.'

Chapter 291

POLICY REFORM FROM THE EARLY 1990S AND CHANGES IN HEALTH STATUS IN INDIA: 1991–2016

C. P. Chandrasekhar^{*} and Jayati Ghosh[†]

Jawaharlal Nehru University, New Delhi, India

INTRODUCTION

This chapter is concerned with examining the changes in health status that occurred during the years following major economic reforms in India and exploring to what extent and how they were related to the policy changes instituted under the new regime.

In an important paper, Cornia (2018, p.1), argued that there have been “episodes of political, economic and social transformation that were expected to generate greater political freedom, economic prosperity and individual wellbeing, but that instead generated substantial increases in death rates, particularly among low income groups.” Cornia identified various mechanisms for such outcomes, including “the unexpected effects of rural-urban migration combined with an inelastic supply of public infrastructure; political reforms carried out in the absence of adequate administrative, legal and redistributive institutions; the introduction of economic reforms under conditions of incomplete or distorted markets and institutions; and the unchecked contact between socio-economic groups characterized by different disease profiles.” In this chapter, we focus specifically on one of these mechanisms, the introduction of economic reforms, to consider the impact on changing health status in India over the past three decades. We ask whether the various reforms introduced in India since the early 1990s had any impact on changing the environment for achieving better health outcomes and explore the extent to which they can be linked to the relatively poor progress in the health status of the bulk of the population.

We begin with a brief description of the main economic reforms in India since 1991, followed in the next section by an examination of the trends in the important indicators of health since 1991. The fourth section considers the differential behaviour of health indicators

in some Indian states, given that there is wide interstate disparity in both levels and trends of health indicators, and a significant part of both health policy and public health expenditure is the responsibility of state governments within India's federal system. The fifth section takes up one particular issue in which public policy appears to be directly related to mortality: agrarian distress and farmers' suicides.

ECONOMIC REFORMS IN INDIA FROM THE EARLY 1990S

While the neoliberal economic reforms in India were accelerated by the balance-of-payment crisis that erupted in mid-1991, the basic thrust of the policy reforms was broadly in alignment with the Washington Consensus. The underlying premise was that the state's economic presence should be substantially reduced, not only with the aim of curbing excessive fiscal deficits, but also to open up new fields to the private sector and do away with the bureaucratisation, overstaffing, and soft budget constraints typical of state enterprise. Imports were to be liberalised, not only to provide the domestic private sector with access to the capital goods, intermediates, and raw materials needed to restructure and become internationally competitive, but also to expose it to the cutting edge of international competition. Domestic deregulation was seen as providing the flexibility required for restructuring and allowing market forces to play their role in disciplining economic activity. Greater freedom was to be provided to international capital, both productive and financial, so as to increase access to foreign finance as well as to exploit the benefits of the improved technology, modern management practices, and the links to international markets that transnational firms offer. To ensure that private initiatives would more than adequately replace the state as the locomotive of growth, tax policies were sought to be rationalised and the tax regime rendered less "burdensome," so that the taxation regime would not act as a disincentive to saving and investing. These parameters determined the large number of policy shifts that, during the 1990s, helped put in place a qualitatively new policy regime in India and gave the liberalisation of that decade its distinctive character.

Reduction of the fiscal deficit was central to both the stabilisation and structural adjustment components of the neoliberal reform package. From the argument that the fiscal deficit of the government should be reduced from the rather high levels in 1991, this led to the enactment of the Fiscal Responsibility and Budget Management Act, 2003 (FRBMA), which sought to bring down the public deficit down to 3% of gross domestic product (GDP) over a specified period. In fact, the goals set by that act have never been achieved. Even the excess deficits reflect various forms of creative accounting, such as not including items that were declared "extra-budgetary," forcing public-sector enterprises to take on debts because of non-payment of dues by the government and forcing them to buy each other's shares to declare greater revenues from "privatisation." These dubious accounting practices have been carried out simply to disguise the actual fiscal deficit, to appear to at least attempt to comply with the act. Nevertheless, despite these sleights-of-hand, the FRBMA has led to certain self-imposed constraints on state fiscal policy. The first is the pressure to reduce expenditures other than those on interest payments, especially the expenditures of the government on subsidies and administration, both of which are considered excessive and reflective of inefficiency. The major item of expenditure that has been targeted to be pruned is the outlay on subsidies, but

success of that endeavour has been mixed. In fact, other expenditures, such as capital expenditure, were cut back even more drastically.

The principal aims of the structural adjustment policies adopted as a part of the reform process were (a) to do away with or substantially reduce controls on capacity creation, production, and prices, and to let market forces influence the investment and operational decisions of domestic and foreign economic agents within the domestic tariff area; (b) to allow international competition and therefore international relative prices to influence the decisions of these agents; (c) to reduce the presence of state agencies in production and trade, except in areas where market failure necessitates state entry; and (d) to liberalise the financial sector by reducing controls on the banking system, allowing for the proliferation of new financial institutions and instruments and permitting foreign entry into the financial sector. As noted earlier, these were all based on the notion that greater freedom given to private agents and market functioning would ensure more efficient and more dynamic outcomes.

For industry, this meant that interventionist barriers to entry of domestic and foreign investors into a number of industries were substantially diluted or eliminated, resulting in what has been proclaimed as a much more competitive environment in the industrial sector. It was hoped that this more competitive environment would in itself induce higher rates and greater efficiency of investment and thereby lead to accelerated industrial growth in both output and employment. An implicit assumption was that the beneficial effects of this would far outweigh any negative impetus of reduced public investment. However, after an initial spurt led by an import-based consumer goods boom, growth rates in the industrial sector slumped once again, and the manufacturing industry did not grow in shares of national income or employment. Liberalisation per se was not enough to ensure high rates of growth of investment and productive activity. Since the middle of the current decade, investment in manufacturing stalled and then declined, reflecting inadequate demand within the domestic economy and declining export demand.

The major policy shift contributing to heightened competition in the domestic market was the liberalisation of the import trade. A distinguishing feature of the economic reforms of the 1990s was the effort to dilute import controls by rapidly reducing the number of tariff items subject to quantitative restrictions, licensing, and other forms of discretionary controls on imports. By now, most of these have since been abolished except in a very few industries. In addition, there were continuous cuts in the tariff rates on a wide range of commodities. By 2001, apart from a very few items, the only form of protection provided to the domestic productive sectors was that offered by tariffs, which were also simultaneously being reduced. The peak tariff rate fell from more than 300% at the start of the 1990s to less than 40% by 2001 and then to around 20% by 2010. By 2017, average applied tariffs were only around 7% (WTO, 2018).

Obviously, given the largely “closed” structure of the Indian economy over much of the post-Independence period, this had very significant effects on patterns of production and viability of different types of economic enterprise. The government’s aim was to restructure production towards areas of international “comparative advantage” (defined in static rather than dynamic terms). These areas were also seen as inherently more labour-intensive, which led to the further prediction that, after an initial brief period of net job loss, such a strategy of trade liberalisation would actually create more employment over time and in more sustainable ways. There are, of course, problems with such an argument. The first is the implicit assumption that international markets in most traded goods are actually free and competitive

and do not reflect the very extensive implicit and explicit subsidies provided by states across the world on various forms of production or the market imperfections created by concentration and centralisation. This is obviously not the case, and therefore the resulting patterns of trade were quite different from those anticipated based on such an assumption. The second false premise is that capital and labour can move (with relatively little cost) from one activity to another and enable structural transformation through trade. But the most significant assumption of all is the implicit assumption of full employment, which has obviously not been met, as well as other crucial assumptions relating to the nature of technology and economic organisation. Recognising the existence of economies of scale and learning effects allows for the possibility of dynamic comparative advantage that require quite different policy responses. Since the basic assumptions underlying trade reform were not valid in the Indian context during this period, it is not surprising that the actual effects of such liberalisation were quite different from those anticipated. The trade strategy has not entailed a major positive shift in the structure and growth of production or exports. Instead, most Indian producers have experienced an erosion of competitive position (in both export and import markets), even as their costs have continued to rise in important areas such as infrastructure and finance.

This trade strategy had a direct impact on agriculture, which grew even more intense over the decades. While the economic reforms did not include any specific package specifically designed for agriculture, the presumption was that freeing agricultural markets and liberalising external trade in agricultural commodities would provide price incentives leading to enhanced investment and output in that sector, while broader trade liberalisation would shift inter-sectoral terms of trade in favour of agriculture. However, there were other changes in patterns of government spending and financial measures that also necessarily affected the conditions of cultivation, often in ways very different from those that were anticipated by the architects of the reform process.

Thus, the post-reform strategy involved the following measures that specifically affected the rural areas: declines in central government revenue expenditure on rural development, cuts in particular subsidies such as on fertiliser in real terms, and an overall decline in per capita government expenditure on rural areas. There were also very substantial declines in public infrastructure and energy investments in rural areas. These were especially marked in irrigation and transport, both of which matter directly and indirectly for agricultural growth and productivity through their linkage effects. The public distribution system for food experienced reduced spread and rising prices, which had a significant effect on household food consumption in some areas of the country and was sought to be reversed through the National Food Security Act 2014. Financial liberalisation measures, including reducing priority-sector lending by banks, effectively reduced the availability of rural credit and thus made farm investment more expensive and more difficult, especially for smaller farmers. And there was significant liberalisation of external trade, first through lifting restrictions on exports of agricultural goods, and then by shifting from quantitative restrictions to tariffs on imports of agricultural commodities. A range of primary imports were removed from state control and thrown open to private agents. Import tariffs were substantially lowered over the decade. Exports of important cultivated items, including wheat and rice, were freed from controls, and subsequent measures were directed towards promoting the exports of raw and processed agricultural goods. Although the proponents of such policies argued that they would lead to an acceleration of output growth in agriculture by increasing market-based

incentives for agricultural investment and output, such an acceleration did not occur. In fact, agricultural growth decelerated compared to the previous decade, and there have been declines in per capita food-grain output and reduced (and more recently negative) rates of agricultural employment generation, in a context of inadequate expansion of non-agricultural income opportunities. The implications of this, specifically related to the agrarian crisis and farmers' suicides, are considered in the fourth section.

Many would argue that financial-sector reform and the associated dependence upon internationally mobile finance capital has been qualitatively the most significant aspect of the reforms. This is because such moves then make the other features of reform inevitable, in that no other measures would be seen as viable since they would be presumed to fail to retain investor confidence. In India such liberalisation touched on diverse aspects of the financial sector's functioning. In the banking sector, which dominates India's financial system, the reform involved measures aimed at increasing the credit-creating capacity of banks through reductions in the statutory liquidity and cash reserve ratio, while offering them greater leeway in using the resulting liquidity by drastically pruning priority sector lending targets. This was combined with greater flexibility in determining the structure of interest rates on both deposits and loans.

In addition, there were structural changes in the banking sector. While the existing public sector banks were permitted to sell equity to the private sector, private investors were allowed to enter the banking area. Foreign banks were given greater access to the domestic market, both as subsidiaries and branches, subject to the maintenance of a minimum assigned capital and being subject to the same rule as domestic banks. Finally, a degree of 'broad-banding' of financial services was permitted, with development finance institutions being allowed to set up mutual funds and commercial banks, and banks themselves permitted to diversify their activity into a host of related areas. The public-development banks were turned into commercial banks, thereby depriving industry of a critical source of patient finance that is willing to invest for the long term (Mazzucato and Penna, 2016). Banks were also given greater freedom in determining their asset portfolios. They were permitted to cross the firewall that separated the banking sector from the stock market and invest in equities, make advances against equity provided as collateral, and offer guarantees to the broker community.

The reforms in the banking sector were accompanied by measures aimed at liberalising financial markets. Companies could freely seek finance through the capital market, subject to the guidelines and regulations specified by the newly created Securities and Exchange Board of India (SEBI). Selected Indian companies were allowed to access international capital markets through Euro-equity shares. A range of nonbank financial companies, including private mutual funds, were allowed to operate. Investment norms for non-resident Indians (NRIs) were liberalised, and portfolio finance companies in the form of foreign institutional investors (FIIs) were allowed to register and invest in India's stock markets, subject to some ceilings that were then continuously relaxed. In addition, the government did away with the higher rate of capital gains taxation that applied to foreign and non-resident India investment in the stock market that departed in a short period of time.

In terms of GDP growth, this strategy was clearly associated with more rapid expansion, as is evident from Table 1. This indicates that the acceleration of the rate of growth was not too significant during the initial years of reform. It was during the period since 2004–05 that India moved on to a substantially higher rate of GDP growth, though the figure for growth after 2011–12, computed using a new series of GDP estimates with 2011–12 as base, has

been the subject of controversy. An important feature of the growth process under reform, and especially during the high-growth years, has been the sectoral distribution of growth, with evidence of deceleration of growth in the commodity-producing sectors. The growth of gross value added (GVA), at constant prices, in agriculture and allied activities has fallen from 6.3% in 2016–17 to 3.4% in 2017–18, that in mining and quarrying from 13% to 2.9%, and that in industry from 7.9% to 5.8%. The growth rates in 2017–18 have risen only in construction (13% to 5.7%); trade, hotels, transport, and communication (7.2% to 8.0%); and financial, real estate, and professional services (6.0% to 6.6%). Meanwhile, conservatism in public spending has meant that GVA growth in public administration and defence has fallen from 10.7% to 10%. And without support from the commodity-producing sectors, GVA growth in electricity, gas, water supply, and other utility services has decelerated from 9.2% to 7.2%.

1951–52 to 1964–65	4.0
1964–65 to 1974–75	3.2
1974–75 to 1984–85	4.1
1984–85 to 1994–95	5.3
1994–95 to 2004–05	6.0
2004–05 to 2012–13	8.1
2011–12 to 2017–18	7.0

Source: Central Statistical Organisation National Income Accounts, various issues.

This focus of growth on a few service sectors and absence of dynamism in the commodity-producing sectors has meant that services account for a significant part of the increment in GVA in recent years. Considering the period since 2011–12, when the current national accounts series became available, we find that while agriculture and allied sectors accounted for just 7.4% of the increase in aggregate GVA over 2011–12 to 2017–18 and industry for 28.5%, services contributed 64.4% (Figure 1).

Figure 1. Sectoral shares in growth of value added at constant prices Between 2011-12 and 2017-18.

Services are of two kinds. Those characterised by high value added per worker (because of high per-worker revenues, such as in IT services, or per-worker state expenditures, such as in some social services) and relatively low absolute employment measures and those with

extremely low valued added per worker, but high absolute employment numbers. The latter kinds of services are the sink for the large workforce unable to find employment in the poorly performing commodity-producing sectors. The high share of services in the increment in GVA points to partly self-fuelling growth of the “new services” and their reliance on low-cost, outsourced domestic services of various kinds, such as logistics, catering, and security. The so-called high productivity services derive their high value added by contracting those operating with low-cost workers in precarious employment.

A significant failure of the reform process was that it did not generate a pattern of growth associated with rapid productive employment generation. Instead, both aggregate employment creation and structural transformation remained sluggish – and in recent years have even backtracked, despite apparently rapid rates of aggregate income expansion. While employment growth did not keep pace with population growth throughout the post-reform years, and the proportion of workers in informal activities without formal employment contracts remained stubbornly high at more than 90%, employment trends appear to have deteriorated further in the past decade. Data from the latest Survey on Employment and Unemployment of the National Statistical Organisation of India suggest that, almost unbelievably, aggregate employment shrank by about 7 million in the period 2011–12 to 2017–18, while the open unemployment rate was at a 45-year high of 6.1%. These extremely weak labour market conditions obviously create adverse conditions for health. And this was associated with substantial increase in inequality over this period, such that a recent study (Chancel & Piketty, 2017) found that income inequality in India is at its highest level since 1922. This had also led to bad health outcomes, because low and unequally distributed incomes tend to be linked with poor nutrition and prevent poor people from being able to access appropriate health services. Fiscal constraints (and the lack of political will) prevented the required expansion of public expenditures in the physical and social infrastructure and amenities that could have led to improving health conditions, thereby accentuating the problem.

HEALTH OUTCOMES IN INDIA SINCE 1991

As India nears the completion (in 2021) of 30 years of the “economic reform” process that dismantled the post-Independence policy structure of state intervention (involving widespread regulation and expanding state presence), health outcomes do not seem to have met even official expectations. The structure of reform was one where growth (reflected in an obsession with GDP) was left to private initiatives “disciplined” by the operations of a liberalised market, whereas advance on the human development front was to be realised through public action. Two factors limited the gains made on the human development front through the pursuit of this strategy. The first was the fact that the trajectory of growth was deeply inequalising, reducing the capacity of a majority to access the services (now increasingly provided at a cost) needed to improve their status in areas like education and health. The second was that the promised “public action” that was supposed to accompany the growth process was not realised, because financial allocations fell far short of requirements as a result of the combination of a lenient tax regime aimed at incentivising private investment

and an emphasis on fiscal conservatism and austerity that was an essential component of neoliberalism.

In 1991, India was far short of providing to its citizens what could be considered a healthy life based on a comparison of health status indicators in similarly placed poor countries. Taking the most summary measure, in the form of life expectancy at birth, India, with a national Figure of 58.4 years, was not performing as well as its South Asian neighbours, especially Sri Lanka (69.6 years), and was way short of many other emerging markets, albeit ones with a relatively higher per-capita income (Table 2).

If we examine more specific data reflective of the success of health interventions and market-mediated availability, such as the infant and maternal mortality rates, the picture is even more dismal. India's infant mortality rate in 1991 of 86.3 per 1,000 live births was better than only that of Nepal, Bangladesh, and Pakistan in the sample of developing countries chosen for comparison and was much cause for concern when compared with neighbouring Sri Lanka, which recorded a creditable Figure of 18.1 per 1,000 live births (Table 3). The situation was similar to the World Bank's modelled estimates of the maternal mortality ratios provided in Table 4.

The problem, however, is not just concerning the initial conditions but also the pace of improvement – in which India fares worse than many poorer countries. In the case of the under-5 mortality rate, for example, Bangladesh and Nepal were worse off than India in 1990, with figures of 143.6 and 141.9, respectively, per 1,000 live births. India recorded a figure of 125.6 that year. But in the 22 years between 1990 and 2012, while Bangladesh registered an annual average rate of reduction of 4.7 units a year and Nepal of 4.6 units a year, India's average rate of decline was 3.2 units. As a result, the former two countries recorded better

under-5 mortality rates than India in 2012, pointing to poor progress in the Indian case despite the other structural and growth potential benefits India possessed (Table 5). As expected, the annual average rate of reduction tends to be low in countries where initial conditions reflect low under-5 mortality rates, such as Sri Lanka, for example. But what is noteworthy is that when India is compared with countries that started at similar or even higher levels of under-5 mortality, the average rate of decline in the mortality figure was lower, resulting in India falling behind those countries in mortality reduction. The experience has been similar with respect to infant mortality as well (Table 6).

In the case of maternal mortality, India's intertemporal record was comparable to that of Bangladesh and Myanmar, but fell short of that of Nepal, while being better than that of Pakistan and Indonesia, which had started with significantly lower levels of mortality (Table 7).

An examination of changes in age-specific mortality rates at the all-India level since 1990–91 reveals a few significant trends. First, two indicators point to shortfalls or inadequacies in health services provision during the years of reform. One is that while under-5 mortality rates have registered declines, starting from 26.5 in 1991, they still remain high, at 9.4 per 1,000 in 2016. The other is that when compared across age groups, mortality rates show a significant rise at a relatively early age, starting at the 45–49 age group and going on to 70-plus. Third, there are significant differences in mortality rates in different age groups between rural and urban areas, with rural areas that are likely to have limited access to quality health resources recording much higher rates. And finally, in both urban and rural areas, gender differentials in mortality rates in almost all age groups are not too significant.

There have been some changes in the causes of death over the first decade of this century. During 2001–03 non-communicable diseases, which were the leading causes of death, accounted for 42% of all deaths. That figure had risen to 49% by 2010–13. Communicable, maternal, perinatal, and nutritional conditions accounted for another 38% of deaths in 2001–03, with that figure falling to 28% during 2010–13. Injuries and ill-defined causes account for 10% each in 2001–03 and 11% and 12%, respectively, in 2010–13. So a shift from communicable to non-communicable disease in terms of proportionate contributions to mortality is visible during those years of high growth.

It is noteworthy that in rural areas the decline in deaths due to communicable maternal, perinatal, and nutritional conditions fell quite sharply from 41% of all deaths in 2001–03 to 29% during 2010–13. In urban areas, however, the decline was smaller in magnitude, starting from a significantly lower figure – from 25% to 22% between these two periods. However, it needs to be said that with more than a quarter of all deaths still due communicable diseases, the problem is still woefully inadequate public health interventions (Motkuri and Khan, 2018). Even in 2010–13, tuberculosis, respiratory diseases, and respiratory infections still accounted for 3.7%, 3.9%, and 7.6% of deaths, respectively; diarrhoeal and digestive diseases for as much as 10%; and perinatal conditions for 5.6%. Meanwhile, cardiovascular diseases rose from 18% of deaths in 2001–03 to 23% of deaths in 2010–13.

The areas in which India's record during the reform years leave much to be desired are maternal and child mortality. Though estimates point to a reduction in the rate of maternal mortality from 556 per 100,000 live births in 1990 to 174 in 2015, the annual rate of reduction, despite fluctuations, has not changed very much over the reform years (Tables 8 and 9). The outcomes on child mortality are more disconcerting. As noted in *The Lancet* (Liu et al., 2019), "An estimated 1.201 million deaths occurred in children younger than 5 years in India in 2015 – the largest number of such deaths among all countries. The number reduced from 2.516 million in 2000, yet despite this progress, India did not meet target 4 of the Millennium Development Goals (MDG 4) of a two-thirds reduction in under-5 mortality rate between 1990 and 2015." The data show that "the leading causes of death were preterm birth complications, pneumonia, and intrapartum-related events. Neonatal sepsis or meningitis, diarrhoea, and injuries were also important causes."

Table 8. Maternal mortality in 1990–2015

Year	Maternal mortality ratio* per 100,000 live births	Maternal deaths	AIDS-related indirect maternal deaths	Live births, 1,000s	Proportion of maternal deaths among deaths of female reproductive age (%)
1990	556 [445–685]	152,000	5	27,430	19.7
1995	471 [396–560]	130,000	53	27,671	16.4
2000	374 [324–437]	104,000	280	27,884	13
2005	280 [240–324]	77,000	520	27,634	9.8
2010	215 [183–255]	57,000	400	26,566	7.6
2015	174 [139–217]	45,000	280	25,794	6.2

Note: MMR and PM are calculated for women aged 15–49 years.

Table 9. Maternal mortality ratio annual rate of reduction (%)

1990–2015	4.6	[3.5–5.7]
1990–2000	4	[1.8–5.6]
2000–2015	5.1	[3.7–6.7]
2005–2015	4.7	[2.9–6.7]

The disparities in the rate of improvement of outcomes point to provision of and access to different kinds of facilities. The fact that deaths due to preterm complications (annual rate of reduction 1.1%) did not change much, even as intrapartum deaths fell substantially over the 15 years ending 2015, show that while measures adopted during delivery had improved, investments and other measures to increase access to and use of institutional facilities for

births and caesarean sections, ambulance support, and so forth, were inadequate. But even access to institutional facilities does not guarantee success, as “the establishment of several hundred district neonatal intensive care units does not appear to have had a noticeable effect on mortality due to preterm birth complications.” (Li Liu et al., 2019, p. e731) On the other hand, the near-halving of under-5 mortality rate (annual rate of reduction of 5.2%) was due to the rapid decline of causes that were addressed with better provision and use of vaccines.

It is worth noting in this context that even official sources now recognise that India is facing a “triple burden of diseases”: inadequate control of communicable diseases, emerging non-communicable diseases (some of which result from changing diet and lifestyles), and new infectious diseases (Government of India, 2015). A significant proportion of these are preventable, which puts the responsibility on public health measures for prevention. However, inadequate public expenditures as well as insufficient intervention for control have meant that India’s aggregate performance with regard to such diseases has been poor.

This intertemporal performance suggests that while initial conditions with respect to health status in India were already relatively poor, India’s record over the reform years fell short of expectations and was also worse than similarly placed countries within the region. Clearly, levels of and changes in per-capita incomes are not the principal determinants of health status outcomes, which can and have been modified significantly by patterns of development and public action. This is remarkable because, as noted earlier, the period under consideration was one in which India recorded reasonable and even high rates of growth and with growth accelerating after 2003. This suggests that the pattern of growth during the reform era and the nature of state intervention were not the most conducive for improving the health status of the population. The adverse effects that state policies have had on the relationship of growth and employment, on the one hand, and on welfare measures and public provision of social services, on the other, were bound to affect livelihoods and the quality of life.

INTERSTATE VARIATIONS IN HEALTH OUTCOMES

India contains such vast regional diversity that it is often very misleading to treat it as one unit. Health indicators in Kerala, for example, have long been substantially better than those in other states, despite Kerala being only a middle-income state within the country. As Table 10 indicates, Tamil Nadu ranks second best in terms of both infant mortality rate (IMR) and maternal mortality ratio (MMR), but that gap with Kerala is large. However, Tamil Nadu achieved this rank through much faster improvement than most other states over the previous two decades. The other states among the top five are Maharashtra, West Bengal, and Punjab, but then the differences with other states become much less. The states with the highest IMR and MMR are Uttar Pradesh, Rajasthan, Assam, Madhya Pradesh, and Orissa. Bihar, Jharkhand, and Chhattisgarh have slightly better IMRs but poor MMRs. Further, the gap between states like Tamil Nadu and Maharashtra, which are on the top, and states like Uttar Pradesh and Madhya Pradesh, which are at the lower end, is significantly large. For instance, the IMR in Uttar Pradesh is more than twice that in Tamil Nadu and the MMR in Uttar Pradesh is almost four times that in Tamil Nadu.

Table 10. Education and health indicators across Indian states

State	Literacy rate (2011)	Expected years of schooling (2011)	Infant mortality rate (2010)	Maternal mortality ratio (2007-09)	Life expectancy (2002-06)
Andhra Pradesh	67.7	9.86	46	134	64.4
Assam	73.2	9.54	58	390	58.9
Bihar	63.8	9.58	48	261	61.6
Chhattisgarh	71.0	9.31	51	269	58.0
Gujarat	79.3	9.79	44	148	64.1

Tamil Nadu	80.3	10.57	24	97	66.2
Uttar Pradesh	69.7	9.19	61	359	60.0
West Bengal	77.1	8.97	31	145	64.9
India	74.0	9.62	47	212	63.5

Source: Sinha (2016).

Disparities in the annual rates of reduction during 2000–15 were significant across states as well. One major and persistent disparity is that between the eight socioeconomically backward states of Bihar, Chhattisgarh, Jharkhand, Madhya Pradesh, Orissa, Rajasthan, Uttaranchal, and Uttar Pradesh, referred to as the Empowered Action Group (EAG) states, and the other states of the nation. As Table 11 shows, life expectancy in the EAG states and Assam was reduced because of much higher mortality in the 0–4 age group and noticeably higher mortality in the 5–29 age groups. As expected, non-communicable diseases such as cardiovascular diseases are less important as causes of death in the backward states as compared with the other states, whereas perinatal conditions, respiratory diseases, diarrhoeal and digestive diseases, and respiratory infections are relatively more important as causes of death in the former. That is, conditions that are addressed more easily with medical health interventions still remain the most important causes of death in backward states (Table 11).

An analysis based on National Sample Survey 71st round data (Kumar & Singh, 2016, p. 269) found that a leading reason for the persisting lag in these states was the inadequate availability and access to public sources of healthcare. According to that study, “the EAG states could ensure access to public sources of healthcare to a limited population (30% rural and 22% urban). Among the EAG states, Odisha performed the best in securing access to public health services to a large proportion of inpatients in both rural (71%) and urban areas (47%), followed by Uttarakhand (61% rural and 31% urban) and Rajasthan (44% rural and 39% urban). The inpatients of Chhattisgarh also reported better accessibility (42% rural and 26% urban) to public sector facilities in comparison to Uttar Pradesh (16% rural and 14%

urban) and Bihar (16% rural and 18% urban). Similarly, the results reveal that accessibility to public sources of healthcare is better in Madhya Pradesh (27% rural and 29% urban) and Jharkhand (25% rural and 20% urban) in comparison to Uttar Pradesh and Bihar.” In addition: “Long waiting time in seeking healthcare from public health facilities is a major public health challenge in the EAG states. A large proportion of inpatients (14% rural and 24% urban) of the EAG states do not access public sources of healthcare as they have to wait for a long time in a queue while seeking these facilities. Surprisingly, due to long waiting in public health facilities 74% of inpatients of rural areas of Uttarakhand do not access these facilities. Similarly, longer waiting time dissuades a large proportion of inpatients of urban areas of Uttar Pradesh (30%) and Bihar (30%) from accessing public health facilities.”

Table 11. Distribution of deaths by age in EAG states and Assam and other states, 2010–2013

	All other remaining causes	22.5	22.5	22.5
	Total	100.0	100.0	100.0

It is evident that public interventions play a major role in determining these varying health outcomes. Basic infrastructure and amenities that are driven by public spending play a huge role in ensuring better health outcomes. For example, Sinha (2016) pointed out that Tamil Nadu is the state with highest immunisation coverage, while the percentage of deliveries assisted by health personnel is highest in Kerala, followed by Tamil Nadu, with other states substantially lower. While the percentage of deliveries assisted by health personnel is about 91% in Tamil Nadu, it is only about 75% in the next state, Andhra Pradesh. The gap with lower-ranking states is much wider: The percentage of births delivered with skilled attendance is less than 30% in Bihar, Jharkhand, and Uttar Pradesh. It is obvious why skilled attendance during delivery is seen as a proxy of maternal health, since immunisation and safe deliveries contribute in major ways to decreasing neonatal and infant mortality, as well as maternal mortality.

AGRARIAN CRISIS AND FARMERS' SUICIDES

The neoliberal reforms from 1991 onward did not really focus on agriculture – instead, the emphasis was put on non-agricultural sectors as the means to both faster economic growth and development in terms of structural transformation. The basic economic strategy pinned its faith on large investments by private corporate capital, and so various controls on such capital, in the form of internal and external regulation, were sought to be removed, and in

addition, over time various incentives were provided to encourage more rapid rates of private investment.

This strategy had very little for small producers, whether in agriculture or other activities. In the early 1990s, it was felt that the devaluation of the rupee already provided sufficient incentive to agriculture, because the expectation was that this would make it more attractive to export crops, which would thereby improve farm incomes. Subsequently, the presumption was that freeing agricultural markets and liberalising external trade in agricultural commodities would provide price incentives leading to enhanced investment and output in that sector, while broader trade liberalisation would shift inter-sectoral terms of trade in favour of agriculture.

But other economic policies and changes in government spending and financial measures had significant implications for cultivation. Four important policy areas that had effects on agriculture related to public expenditure, food management, access to institutional finance, and trade liberalisation. Initially, there were absolute actual declines in central government revenue expenditure on agriculture and rural development. Thereafter, there were cuts in particular subsidies in real terms, such as on fertiliser, and the 1990s experienced an overall decline in per-capita government expenditure on rural areas. There were also very substantial declines in public infrastructure and energy investments that affect rural areas, especially in irrigation and transport. In addition, financial liberalisation measures, including the emerging scope of what was designated as priority-sector lending by banks, effectively reduced the availability of institutional credit for farmers. Bank branches, accounts, and lending to agriculture all decelerated, and in some states they showed declines. This forced many cultivators, particularly smaller farmers, tenant farmers, and those without clear titles to land, to seek recourse from informal channels of credit like input dealers and traditional moneylenders. All this made farm investment and working capital for cultivation more expensive and more difficult, especially for smaller farmers.

Inputs for cultivation became a particular concern, as public extension services no longer provided adequate information, access to subsidised quality inputs was reduced, and various subsidies were sought to be lifted. Spurious seeds, greater reliance on expensive seeds provided by large domestic and multinational companies that involved “terminator genes” that did not allow subsequent local reproduction, problems with price and quality of fertiliser and pesticides and excessive use of both, often in wrong proportions – all of these became frequent problems that affected the quantity and quality of output as well as the margins available to farmers.

All these forces led to a slowdown in agricultural growth and, by the late 1990s, widespread distress in the countryside. The most extreme form of expression of such distress was in the spate of farmers’ suicides, which occurred typically when heavily indebted farmers whose farms had lost viability could find no other recourse. By the mid-2000s, it was evident that the problems facing agriculture were severe and would require prompt policy attention. The Congress-led United Progressive Alliance (UPA) government that came to power in 2004 had in fact made the problems facing cultivation and rural distress generally a major plank of their electoral campaign. They sought for some years to reverse the pattern of declining public spending, with increased public investment on irrigation and rural infrastructure, and more central government spending on agricultural research and extension, as well as increased credit to rural areas. These positives were very limited in extent, but they did

partially reverse the trend of rural decline, aided by high and rising prices of agricultural goods in global trade.

Liberalisation of external trade became an important element of the reform process, first through lifting restrictions on exports of agricultural goods, and then by shifting from quantitative restrictions to tariffs on imports of agricultural commodities. A range of primary imports was liberalised and thrown open to private agents. Import tariffs were very substantially lowered over the decade. Exports of important cultivated items, including wheat and rice, were freed from controls, and subsequent measures were directed towards promoting the exports of raw and processed agricultural goods. Indian agriculturalists were increasingly exposed to global competition even as the protections they had in terms of support prices, input assistance, and public extension services were gradually being reduced or even withdrawn.

For Indian agriculture, this led to a peculiar combination of low prices and output volatility for cash crops. While output volatility increased especially with new seeds and other inputs, the prices of most non-food-grain crops weakened, and some cases plummeted. Further, farmers were squeezed as input costs kept rising, either because reduced subsidies and rising input prices, or because of the need to use more and more inputs (such as seeds, fertiliser, and pesticides) to achieve the same levels of output. This reflected not only domestic demand conditions but also the growing role played by international prices as a consequence of greater integration with world markets in this sector. Indian farmers had to operate in a highly uncertain and volatile international environment, effectively competing against highly subsidised large agribusinesses in the developed countries.

In recent years, farmers' movements and farm loan waivers in different states across India have driven home the fact that the viability of agriculture is under challenge. This is surprising, since the comprehensive framework for reviving agricultural production, introduced in response to the agricultural crisis in the mid-1960s, is in principle still in place. There were many components to that framework besides the adoption of green revolution technology. The most relevant aspects of this discussion are the measures that were aimed to ensure the viability of agriculture.

The measure directly relevant to the purpose was the promise to procure, at a pre-specified, cost-plus remunerative price, any supplies of identified crops that farmers chose to sell to the government. With these minimum support prices (MSPs) revised each year, this measure was aimed at ensuring that there was a rising floor to agricultural prices, which would stabilise income increases and guarantee farmers a return on investments that would help raise productivity. There were two problems deriving from this measure that needed to be addressed: managing the supplies procured by the government and insulating the consumer from increases in market prices at rates much higher than the procurement price. With respect to the first, the government decided to dispose of the stocks it procured and accumulated through the public distribution system, which was already in place to manage regional differences in food grain availability. This was to be done at affordable prices, which given the procurement, storage, and transportation costs incurred by the government, had to include a subsidy that moderated prices paid by the consumer. Thus, it was hoped that agricultural production would be incentivised, farmer incomes would be stabilised, and consumers would be protected against agricultural price inflation.

Many years have passed since this system was first put in place, so countrywide coverage should have been ensured and the government should have accumulated enough experience to

implement it without difficulty. The result should have been a viable agriculture and satisfied consumers. But instead, there is clear evidence that crop production is increasingly unviable. There are two reasons for this: the fact that procurement prices have not kept pace with actual costs of cultivation, rather than the notional national averages computed for the purpose, and the fact that procurement operations are so limited (covering only an estimated 6% of farmers) and, in any case, do not really work other than for the major food grains, so that they do not provide the expected floor prices for markets.

In recent years, annual increases in the MSP have been smaller than earlier with farmers complaining that support prices have not kept pace with costs. A research report from the rating agency CRISIL found that the average annual growth of the MSP fell from 19.3% in the period 2008-09 to 2012-13, to only 3.6% in the period 2013-14 to 2016-17 (Chandrasekhar and Ghosh, 2017). This deceleration added significantly to farmers' distress.

In addition, the gradual liberalisation of trade in agricultural commodities has increasingly linked domestic to international prices. Overall, policies deregulating input prices, curtailing subsidies, freeing imports, and lowering import tariffs have subjected agriculturists to rising costs and competition from low-cost imports. This is true across crops, including those crops supposedly under the MSP. This has also meant that in poor harvest years, farmers are not necessarily compensated by an increase in crop prices, while in bumper years, low prices would hit their net incomes, depending on how global prices move. Farmers can lose out as a result of falling market (as opposed to procurement) prices in good harvest years, but not gain in terms of higher prices (even if affected by lower output and revenues) in bad or indifferent monsoon years.

As a result of all of these factors, the viability of crop production has been eroded and farmers hit by slowly rising or falling market prices and/or rising costs find their net returns and income squeezed. An estimate, based on the official National Accounts Statistics, indicates that over the 3-year period 2014-15 to 2016-17, the income per head of the agriculture-dependent population increased by 16% in nominal terms. Over the same period inflation based on the Consumer Price Index for rural India rose by 16.3%. This implies that the real, inflation-adjusted incomes of the agriculture-dependent population have stagnated. A further consequence is that farmers taking working capital and/or consumption loans, as well as loans for investment, are unable to pay off their debts.

There is a further problem that public procurement operations do not reach all farmers and all crops, even for commodities with officially declared MSPs. There are regions of the country where the procurement programme is weak and not accessible to many farmers; there are constant complaints that procurement operations are too tardy, brief, and inadequate to be of real benefit in ensuring a minimum price for farmers. An official assessment conducted in 2010-11 found that, while there were significant regional variations, on average the awareness and use of the MSP programme was high. Yet, sales can occur at prices below MSP partly because of tardy procurement and partly because trade and other policies can depress market prices in good harvest years. The latter transpires, for example, because the government, which fears inflation that may hurt corporates and vocal urban consumers, often chooses to address production shortfalls and actual or potential price increases by releasing accumulated stocks and augmenting domestic supplies with imports from abroad. This dampens price inflation. On the other hand, in good harvest years, neither are minimum support prices increased adequately to ensure a floor price that covers costs and offers a remunerative return, nor is enough procured to ensure that even the MSP offered serves as a

floor for market prices. Thus, market prices have typically been below the MSP for many commodities in many markets.

There were other sins of commission, as demonetisation destroyed rural markets and demand for farmers for a prolonged period, and the imposition of the Goods and Services Tax (GST) added to their cultivation costs. Demonetisation was a severe blow to farmers, as they found it very difficult to sell their crops or access the required inputs. It led to a prolonged collapse in rural livelihoods and demand. This has persisted to the point where even when there is high output because of a good monsoon, farm incomes do not rise because of low prices. The poor implementation of the GST has added to the travails of small and medium enterprises and further affected demand for agricultural produce, leading to persistently low crop prices.

In this bleak context, the expected improvements in crop insurance have also not materialised. Instead, the revised crop insurance scheme has essentially profited private insurance companies. Farmers and state and central governments have paid out increasing amounts as premiums for insurance but have not received the expected compensation when required because of rigid rules about claim settlement. Farmers reeling under dry spells or sudden hailstorms that destroy standing crops are provided no compensation for their losses. A further blow has come to on-farm non-cultivation activities like livestock rearing, which has saved farmers from penury and now accounts for nearly one-third of agricultural value added. This has come under threat from cow vigilantes, who are allowed and even encouraged to run riot and lynch innocent people, and this has generally damaged the livestock trade. As a result, older cattle are simply released by farmers who cannot bear the cost of their upkeep, and the menace of stray cattle roaming the fields has become another factor contributing to the increased costs borne by farmers.

This massive agrarian distress has found some outlet in large protests by farmers across the country, but is more worryingly reflected in a spate of farmers' suicides across the country, especially in the dryland regions that are the worst affected by climate change and rising costs. While recent data on farmers' suicides have not been released, evidence from the Crime Record Bureau suggests that between 1995 and 2012, close to 300,000 farmers committed suicide in the country (Nagaraj, Sainath, Rukmani, and Gopinath, 2016). Even that number is likely to be a significant underestimate, because the major states of Tamil Nadu and Rajasthan, as well as some smaller states, did not report any suicides at all in some years. Further, the stringent definition of farmer based only on land titles meant that many suicides were not recorded as farmers' suicides. As Nagaraj et al. (2016, p. 57) noted, "this often left out a genuine farmer from the count. For example, a tenant farmer who leased in land and hence did not have a title to the land, or a farmer whose land title was in his father's name, or a woman farmer whose land title was in her husband's or father-in-law's name, all could be denied the status of a farmer."

The data suggest that an overwhelming proportion — nearly 85% — of farm suicides are by male farmers, and young farmers account for nearly 30% of the total. The problem of farm suicides has been especially intense in some pockets of certain states: The Vidarbha region in Maharashtra, the Deccan and Hyderabad-Karnataka regions in Karnataka, and the Telangana and Rayalaseema regions in Andhra Pradesh and Chhattisgarh, as well as Wayanad in Kerala (Nagaraj et al., 2016). Most of these sub-regions constitute a contiguous region in the heartland of India. This is a relatively backward region, with poor infrastructure, and very water-stressed with low levels of surface irrigation and scanty, uncertain rainfall. Crop

diversification has added to instability and vulnerability because many of the cash crops that farmers have turned to require groundwater, which is increasingly scarce. This, combined with worsening soil quality because of the increased use of chemical inputs over time, has become associated with falling yields, even as output prices have become more volatile and have not kept pace with rising input costs. This leads to a scissors crisis in the countryside, when initial accumulation of debt for cultivation becomes impossible to repay, and the burden of mounting debt – and finally, the inability to access fresh credit – become the proximate causes of the desperation that leads farmers to take their own lives.

This in turn suggests that the problem of farm suicides is particularly acute when there are pre-existing conditions of very high vulnerability in the region and an absence of alternative livelihood opportunities. Combined with the severe agrarian crisis (largely policy-driven as we have noted above), a toxic mix results that leads to higher mortality among those who find that they simply cannot cope with the material pressure brought about by the collapse in the viability of cultivation.

ABSTRACT

Advances in the microbiological safety of foods have been largely driven by public demand in response to disease outbreaks. A vast array of possibilities has emerged straightforward, being biopreservation the most suitable alternative to please consumers claims for healthier and “greener” foods. Biopreservation uses microorganisms, generally lactic acid bacteria (LAB) as protective cultures (PC). LAB can be added not only to prolong the shelf-life but also to preserve the microbial and/or sensorial quality of food products. The microbial antagonism of LAB against undesirable microorganisms has been attributed in many cases to the effect of one or synergism between several mechanisms, such as competition for nutrients, and production of different metabolites, including bacteriocins. Having GRAS status, LAB-PC can be safely added to foods. Advantages of PC include additive-free preservation, natural image, and food safety improvements. Hundreds of strains from many LAB species have been extensively studied for the preservation of foods showing promising results. The objective of this chapter is to describe current methods and developing technologies for the application of LAB-PC in food products throughout the world. The benefits of new technologies and

their industrial limitations are also presented and discussed. Information given will provide an integrated approach on this topic.

INTRODUCTION

Food matrices are prone to microbial colonization due to their nutritional compounds. Some of these microbes are responsible for food spoilage, and some others are food-borne pathogens which can cause serious health problems once consumed (Varsha & Nampoothiri, 2016). Hence, it is necessary the implementation of adequate technologies to preserve and prolong the shelf-life of food products as well as the health of consumers. Moreover, there is a rising consumer demand for chemical preservative-free products, which results in a perfect opportunity for the implementation of natural additives with antibacterial and antifungal properties.

Among the new approaches, the so-called biopreservation stands out as a promising alternative, specifically the protective cultures (PC) incorporation into food matrices. Microorganisms that produce inhibitory substances, are able to compete against spoilage bacteria and fungi, and extend food shelf life, are consider as PC (Alexandraki et al., 2013; Fernández et al., 2017). The practice of PC inoculation into food matrices is the conception of the biopreservation approach.

Lactic acid bacteria (LAB) have been used traditionally as starter cultures in fermentation processes, being natural inhabitants of fermented food products. Besides, their implementation provides several technological advantages (Bourdichon et al., 2012). LAB incorporation also results in properties changes of the matrix that are non-beneficial for pathogenic and spoilage microorganisms. Furthermore, considering their GRAS (Generally Regarded as Safe) status (EFSA, 2011), LAB become a potential perfect group to be regarded as PC contributing to biopreservation (Divya et al., 2012 a,b).

Lactic acid is the main metabolic end-product from LAB, as a result of carbohydrates degradation. Its production causes a pH decrease, preventing undesirable microorganism proliferation. Lactic acid together with carbon dioxide, hydrogen peroxide, acetoin and other organic acids, all products from LAB metabolism, induce physicochemical changes on food matrices which create a disadvantageous environment for the development of spoilage and pathogenic fungi and bacteria (Deegan et al., 2006). Despite LAB metabolism products have been studied throughout, being their beneficial effects widely known, other LAB molecules have gained newly interest. Among them, bacteriocins are bioactive peptides ribosomally synthesized that have antimicrobial activity against other bacteria (Field, Ross & Hill, 2018). Bacteriocins are produced by many Gram-positive and Gram-negative species (Riley & Wertz, 2002). In spite of this, the ones produced by LAB are of particular interest to the food industry. LAB bacteriocins demonstrated antagonistic action against many food spoilage and pathogenic microbes, in consequence they are an important alternative to chemical additives, prolonging food shelf life, improving safety and preserving quality of food products (Gálvez et al., 2007; Field, Ross & Hill, 2018). Likewise, as mentioned before, many bacteriocinogenic LAB have GRAS status, which make them potentially applicable to food products being non-toxic to consumers and even enhancing health effects. Beside small metabolites, also peptides with antifungal activity have been reported as resulting from LAB

bioactivity. These antifungal peptides are not produced *de novo* by LAB; however, they are produced during proteolysis of proteins present in their surroundings (Siedler et al., 2019).

The objective of this chapter is to describe current methods and developing technologies for the application of LAB-PC in food products throughout the world. The benefits of new technologies and their industrial limitations are also presented and discussed. Information given will provide an integrated approach on this topic. Table 1 is presented herein as a brief sample of the magnitude of the diversity of LAB species, target microorganisms and food matrices comprised within this biopreservation approach.

SCREENING METHODOLOGIES AND STRAIN SELECTION FOR FOOD BIOPRESERVATION

LAB bacteriocins play an important role in the future of food biopreservation. Their narrow killing spectrums and their antimicrobial mechanisms distinguish them from traditional antibiotics. These particular characteristics infer an alternative to fight against drug-resistant bacteria, preserving and prolonging food shelf-life and also decreasing antibiotics ingestion by the consumers, fulfilling consumer demands for more natural and chemical preservative-free products (Cavera et al., 2015; Kaskoniene et al., 2017; Zou et al., 2018).

Bacteriocin-producing LAB strains are isolated from diverse sources, but it is considered that those isolated from a certain matrix constitute the best candidates for biopreservation in that particular matrix, since they have better adaptability to the source environment than LAB isolated from other sources (Castro et al., 2011). In recent years bacteriocins have been discovered from various sources, particularly fermented food products (Castro et al., 2011; Abdel-Halim et al., 2013; Gao et al., 2015; Gautam & Sharma, 2015) but also fish (An et al., 2015), chicken intestines (Rani et al., 2016), soil (Smitha & Bhat, 2013; Lim and Balolong, 2016), human body and its excrement (Lakshminarayanan et al., 2013; Wannun et al., 2014; Maldonado-Barragán et al., 2016) and citrus (Noda et al., 2015), among others. However, in the USA and Canada, the only bacteriocins commercially available are pediocin, produced by *Pedococcus* (*Ped.*) *acidilactici*, Micocin®, a blend of three bacteriocins (carnocyclin A, carnobacteriocin BM1, and piscicolin 126) produced by *Carnobacterium* (*Cb.*) *maltaromaticum* UAL307, and nisin, produced by *Lactococcus* (*Lc.*) *lactis*. Considering these commercial bacteriocins, nisin is the only one approved by the FDA as a food preservative (Martin-Visscher et al., 2011; Huang et al., 2016; Zou et al., 2018).

Hence, as a result of the multiples sources in which bacteriocins can be found, the processes implied in their discovery are very complex and significant resources and time must be invested in the screening, identification, purification, and characterization stages (Kaskoniene et al., 2017). Then, it has become a necessity the development of novel and faster methods to search new bacteriocins as an alternative to the traditional slower and laborious ones.

Traditional screening methodologies for antagonistic activity of bacteriocins, like disc-diffusion, agar well diffusion and spot-on-lawn assays, uses strains in the exponential phase of *Escherichia* (*E.*) *coli*, *Staphylococcus* (*S.*) *aureus* or *Listeria* (*L.*) *monocytogenes* as indicators to inoculate a soft agar culture media (Pingitore et al., 2007; Song et al., 2014a; Pasteris et al., 2014; Gao et al., 2015; An et al., 2015; Maldonado-Barragán et al., 2016). Samples are centrifuged to obtain free-cells supernatant possibly containing the bacteriocin if

the evaluated bacteria are bacteriocinogenic. With a plastic straw, wells are created on the inoculated soft agar media and they are filled with the supernatant or with a purified extract for the spot-on-the-lawn assay (Zou et al., 2018). After incubation, the presence of a clear zone around the wells is considered as a positive inhibitory effect, and its activity is related to the measure of the area of these inhibitory zones. Even though the positive results are easy to identify and discriminate from negative ones, these colonies based assays turn out to be time-consuming since the samples screened are often quite numerous.

One of the novel methods is the PCR array assay developed to identify the presence of genes that codify for bacteriocin production on LAB isolated from food samples. This screening methodology is based on the comparison with known bacteriocin-related genes from the NCBI GenBank database (Macwana & Muriana, 2012; Juturu & Wu, 2108). However, PCR-based methods require the design of primers for each bacteriocin-producing strain since different strains contain different gene sequences that codify for bacteriocin production (Zou et al., 2018). Therefore, PCR-based methods are user-friendlier but also time-consuming. Another new screening methodology is the multi-well plate protocol for bacteriocin detection and it is based on an *in vivo* screening platform that uses 96-well plates and fluorescence imaging analysis to identify bacteriocins from natural sources (Son et al., 2016). The simplicity, fastness, reliability and the high cost-effective ratio of this method are the main advantages against traditional ones.

Once the screening process is complete, the identification of bacteriocin-producing strains is the next step. Normally, the identification of bacteriocin-producing species and strains is based on physiological and biochemical features and 16S rDNA gene sequences (Barbosa et al., 2014; Zhu et al., 2014; Gao et al., 2015). Subsequently after the identification comes the most critical and complex step, purification. This process implies an intensive labor and it is also quite time wasting. Purification of bacteriocins is directly related with applications, purity and price of the end product. The methodology applied to purify bacteriocins depends on the features of each particular bacteriocin, so there is not a single method suitable for all of them and each applied technique has its advantages and disadvantages (Sabo et al., 2018; Zou et al., 2018; Juturu & Wu, 2108). Afterward the screening, identification and purification phases, the characterization of bacteriocins is the last step. There are novel methods, capillary electrophoresis-mass spectrometry designed by Catala-Clariana et al., (2010) for the identification of bioactive peptides in hypoallergenic infant milk formula and, the micellar electrokinetic chromatography, developed by Soliman & Donkor (2010) to quantify nisin on food products. These methods possess the advantage of being faster, more sensitive and efficient than traditional ones.

As mentioned before, the best candidates as biopreservatives on a given matrix are the strains isolated specifically from that matrix, although not always the bacteriocin-producing LAB discovered from a given source is applied on the same source. Hence, an additional and necessary step is to prove the strains on different model mediums, changing certain conditions to determinate the adaptability of the strains to the new environment and confirm the production of the bacteriocin on those conditions, the so-called selection phase.

Selection consists on examination of the strains that exhibited inhibitory activity on the screening stage, and determinate their survival in simulated conditions, such as starvation, presence of NaCl and bile salts, low pH and high temperatures (Matamoros et al., 2009). Another important aspect is to confirm the maintenance or improvement of the sensory, chemical and physical properties of the target matrix since LAB may have negative effects in

different types of food and contribute to food spoilage (Gram et al., 2002; Maragkoudakis et al., 2009). Then, innocuousness is also a factor to take into account, specifically no biogenic amine production and antibiotics resistance. As an example, in Wessels & Huss (1996) research work, some selected strains presented good efficiency in model medium but cannot be applied in seafood because their growth was inhibited by this low-sugar and low-temperature environment, and even could spoil the product.

Summarizing, there are many methods to select, identify, purify and characterize bacteriocin-producing LAB strains in search for the best candidates as biopreservatives. Even though there are no severe rules on the order of the steps to follow or the methodologies to implement, the chosen method must be in accordance to the future application together with the enhancement of food safety and quality.

LIMITATIONS AND FURTHER CONSIDERATIONS

Despite the fact that LAB can produce a variety of compounds with antimicrobial activity, the amounts of individual compounds produced by LAB are often insufficient to sustain the inhibitory phenotype, which is most likely to arise from synergistic or additive bioactivity of the blend of compounds. Thus, identification of new antimicrobial compounds is hampered by their occurrence in low amounts in complex matrices. Moreover, they may not exert inhibition *per se*, which hinders the identification by fractionation techniques. According to Siedler et al., (2019), new approaches are needed to identify and study these complex relationships. Furthermore, knowledge on the physiology of the spoilage organisms is required to understand the mechanisms behind the bioactive compounds.

The main drawback in LAB-PC application into food is the inherent antimicrobial activity loss due to interactions with ingredients and/or processing driven physicochemical instability. Peptide function can be affected by several factors, such as fat content, proteolytic degradation, polar or non-polar food components, pH (which influences the solubility of the bacteriocin) and sodium chloride concentrations, among others. To overcome these obstacles, many bacteriocins have undergone several bioengineering strategies to improve bacteriocin efficacy in the food environment. These strategies comprised a wide array of alternatives, from solubility enhancement (Rouse et al., 2012) to new bacteriocin biosynthetic gene clusters which could be used to guide the bioengineering of new and existing peptide structures (Song et al., 2014b; Sun et al., 2015). The driving force behind these scientific facts is that bioengineered strains which have been tailored through food-grade approaches are not considered genetically modified microorganisms (GMMs) and can be directly added to food (Field et al., 2018). To expand these concepts, the reader would find interesting the reviews from Field et al. (2015), and Ramu et al., (2015).

Among the emerging potential roles for bacteriocin-producing LAB, one of the most outstanding is in functional foods where they will be playing a health-promoting task beyond the biopreservative one. The use of multipurpose bacteria will enable to market food products with an over-the-counter formula that could provide, for instance, a positive modulation of the gastrointestinal (GI) microbiome. As an illustration, a study showed that the strain *Lactobacillus (Lb.) salivarius* UCC118 was able to modify the GI microbiota in diet-induced obese mice whereas its bacteriocin-free derivative did not exert this effect (Murphy et al.,

2013). Conversely, many LAB strains with proved probiotic activity, intended at a beginning to be used as health enhancers, are being under study in order to expand their utility to PC. *Lb. sakei* CRL 1862 comprises a good example of this fact, being a well-known antihypertensive biopeptide producer, it had been proved to control food pathogens (*L. monocytogenes*) colonization on food-industry surfaces (Pérez Ibarreche et al., 2014, 2016).

APPLICATIONS OF PROTECTIVE CULTURES IN MILK AND DAIRY PRODUCTS

Milk and dairy products owe their excellent growth medium conditions to their highly nutritious nature. As a matter of fact, microbial contamination of milk and dairy products is a worldwide problem. Currently, foodborne illnesses from consumption of dairy products have been mainly related to *Campylobacter* (C.) *jejuni*, *E. coli* 0157:H7, *L. monocytogenes*, *Salmonella* spp., *Yersinia* (Ye.) *enterocolitica*, and *Bacillus* (B.) *cereus*. Moulds, mainly species of *Aspergillus*, *Fusarium*, and *Penicillium*, can grow in milk and dairy products. Under the appropriate conditions, these moulds may produce mycotoxins which can be a health hazard. Contamination of raw milk comprises the main microbiological hazard associated with dairy products; pathogens like *S. aureus* may be part of the resident microflora of the living animal, whereas other pathogens such as *E. coli* 0157:H7 or *Salmonella* spp. may originate from faecal contamination during initial milk collection. Despite the many methods applied to control it, contamination post processing can also happen in every stage of the product shelf-life, such as transport, storage and handling. LAB occur naturally in foods and have a long history of safe use in dairy industry. Lack of health risk concerns make them the best candidates for biopreservation and a great alternative to the use of chemical preservatives in dairy products, where they can be introduced as part of the fermentation process or as adjuvant cultures. A number of applications of bacteriocin-producing LAB have been reported to successful control pathogens in milk, yogurt, and cheeses (Silva et al., 2018). Applying bacteriocin-producing LAB strains as antibacterial starter cultures and PC may confer an advantage over the use of semi-purified/purified bacteriocins as much as they are adsorbed into food matrices and are easily degraded, which results in a loss of antibacterial activity.

Anti-listerial activity of many LAB strains has been exploited to control *Listeria* growth in different ripened and fresh cheeses (Coelho et al., 2014; Ibrahim et al., 2017; Silva et al., 2018), while their ability to exert antifungal activity has been optimally used to preserve fermented milk, cheeses and yogurt (Mieszkina et al., 2017; Mosbah et al., 2018; Leyva Salas et al., 2018). Studies described herein have been selected from a vast amount of scientific reports taking into consideration their relatively novelty and groundbreaking practices.

Milk and dairy products are recognized as a good source for the isolation of bacteriocin-producing LAB. Accordingly, donkeys' milk has been a subject of research in recent years, even though its nutritional and therapeutic properties have been recognized since ancient times. Resembling human milk in many ways, donkey milk is recommended as a substitute for individuals presenting cows' milk protein allergy. Aspri et al., (2016 a, b; 2017) had isolated LAB from raw donkey milk and characterized the strains by phenotypical and molecular methods. Besides, they evaluated their technological properties and safety

characteristics as potential starter or adjunct cultures in the production of fermented dairy products. Based on these features, 79 strains were selected and analysed for inhibitory activity against spoilage bacteria and foodborne pathogens. Amongst them, 3 strains belonging to *Enterococcus* (*Ec.*) *faecium* displayed antimicrobial activity against *L. monocytogenes*, *S. aureus* and *B. cereus*. Bacteriocins produced by these strains were tested for their capability to control post-processing contamination and growth of *L. monocytogenes* during refrigerated storage of artificially contaminated fresh whey cheese; two of them (*Ec. faecium* DM 224 and 270) were bactericidal while one was bacteriostatic (*Ec. faecium* DM 33). These strains were tested in a food model and showed a good performance within the cheese matrix, thus they have a promising perspective for biopreservation.

Cheese is considered to be one of the foods most frequently contaminated with *L. monocytogenes* (Aspri et al., 2017). In particular, blue-veined and mould cheeses such as Brie, Camembert, Danish Blue, Stilton and Gorgonzola represent a suitable substrate for the growth of this pathogen (Ramaswamy et al., 2007). The famous Italian PDO Gorgonzola cheese is made using pasteurized cow's milk inoculated with thermophilic cultures (*Streptococcus thermophilus* and *Lb. delbrueckii*), yeasts and, finally, *Penicillium* spp. which confers the typical blue-green veined. Albeit different physical treatments had been studied to control *Listeria* in Gorgonzola rinds, irregular and rough surfaces hampered treatment efficacy and imparted visible changes in the aspect of the rinds. As a consequence, the use of LAB-PC resulted in a promising alternative to limit the growth of *L. monocytogenes* and *L. innocua* on Gorgonzola surface during ripening process (Morandi et al., 2019). The anti-*Listeria* activity differed among the LAB strains and it was *Listeria* biotype-dependent. Amongst 27 strains, *Carnobacterium* SCA, SCB, *Lb. plantarum* NA18, *Lb. sakei* SCC, *Lc. lactis* FT27, N16 and SV77 were selected for their marked anti-*Listeria* activity. When *Listeria* was inoculated on the cheese surface at the end of ripening process (after 50 days; pH: 6.7), only *Lc. lactis* FT27 exerted a significant inhibition on the growth of the two *Listeria* species if the cheese was strictly maintained at 4°C. Hence, this research highlighted that the susceptibility of *Listeria* biotypes to LAB antimicrobial activity is strain-dependent, thus a blend of different LAB strains could represent an effective tool to develop PC for blue-veined cheeses. Seemingly, Mills et al., (2017) proposed a multi-strain approach to tackle this problem. They generated single- and double-bacteriocin-producing cultures of *Lc. lactis* CSK2775 with the capacity to produce the class I bacteriocins lacticin 3147 (lacticin), nisin A (nisin), or lacticin and nisin. This multi-bacteriocin producer was used in combination with plantaricin from *Lb. plantarum* LMG P-26358 to create a cheese starter system.

When PC are meant to be incorporated into a cheese making process, one of the main aspects to be aware of is their contribution to the sensory profile of the final product. The application of new strains to the cheese making process requires a positive sensory acceptance by the consumers. Consequently, regardless of the antimicrobial efficiency of the culture, the generation of volatile compounds (possibly off-odors), and/or high acidification (potential off-flavors) have to be checked and control throughout the cheese manufacture and ripening. In a study by Coelho et al., (2014), 8 bacteriocin producer strains identified as *Lc. lactis* (1) and *Ec. faecalis* (7) were assessed in order to identify those with the greatest potential in reducing *L. monocytogenes* in fresh cheese. A non-trained panel evaluated the attributes acidity, salty taste, firmness, flavor and general acceptability of cheeses made with the bacteriocin-producer strains. All cheeses made with LAB cultures were found to have flavor, salty taste and general acceptability comparable to the control cheese made without

any PC, i.e., no significant differences from control cheeses were found among the sensory attributes tested. According to Pereira et al., (2011), microorganisms inoculated in cheeses made with cows' milk do not exert any influence on the flavor of the cheese in the early days of ripening, which confirms the results obtained in the aforementioned study since LAB-PC were intended to be applied to fresh cheeses with short ripening periods. Regarding bacteriocin activity, its availability comprised the determining factor for an *in situ* antibacterial action. Hence, bacteriocin-like activity should be produced at sufficient levels and be active enough during cheese manufacture and storage. Results derived from this study showed that *in situ* bacteriocin producers clearly showed a high antilisterial activity in fresh cheese made with the *Enterococcus* strains. The *Lc. lactis* strain tested produced lacticin 481, which proved to be less effective in reducing *L. monocytogenes* (Coelho et al., 2014). In accordance to the latter study aims, *Lb. rhamnosus* 131RZFAUU was tested in Domiati soft cheese as a PC against *S. aureus* without affecting flavor acceptability of final product. This LAB-PC was selected among three potential candidates which were analyzed separately and all together. Interestingly, no negative sensory properties were observed by the panelists in fresh cheeses made with LAB strains as a single culture. Conversely, unacceptable flavor was observed in Domiati cheese made with a combination of three strains (Ibrahim et al., 2017).

Ricotta fresca is a whey cheese susceptible of secondary contamination mainly due to its naturally poor competitive microflora and composition, inherent physical and chemical properties and the absence of preservatives. *Pseudomonas* spp, yeasts, molds and *Enterobacteriaceae* comprise the main psychotropic microorganisms usually found in refrigerated whey cheeses (Pala et al., 2016). The use of biopreservatives against these psychotropic spoilage microorganisms was preliminary assessed by Spanu et al., (2017, 2018) on the surface of MAP *ricotta fresca* during refrigerated storage. A commercial biopreservative, Lyofast CNBAL, comprising *Carnobacterium* spp. was tested against *Pseudomonas* spp. This was the first successful attempt to use biopreservatives against psychotropic spoilage microorganism in sheep ricotta cheese.

Selected LAB strains (as in fermentation) or the bioactive compounds purified from the culture medium can be exploited as efficient alternatives for food preservation. Eleven antifungal *Lactobacillus* strains, isolated from cow and goat milk, were fully characterized by Delavenne et al., (2013) using molecular and phenotypic methods. Their antifungal activities were tested in milk and yogurt, against fungal species (*Debaryomyces hansenii*, *Kluyveromyces lactis*, *K. marxianus*, *Penicillium brevicompactum*, *Rhodotorula mucilaginosa* and *Yarrowia* (Y.) *lipolytica*) commonly involved in the spoilage of dairy products. The antifungal strains belonged to *Lb. paracasei*, *Lb. rhamnosus*, *Lb. zeae* and *Lb. harbinensis* species and showed different acidifying and growth capacities in milk. The antifungal activity in milk developed by lactobacilli had a strain-dependent activity spectrum. A very strong antifungal effect in yogurt was displayed by *Lb. harbinensis* against all tested fungi as compared to control. Accordingly, the strain *Lb. harbinensis* K.V9.3.1Np showed a remarkable antifungal activity for the bioprotection of fermented milk without modifying their organoleptic properties (Delavenne et al., 2015). In keeping with these findings, Mieszin et al., (2017) studied the action mechanism of this bioprotective strain against the spoilage yeast *Y. lipolytica*. The tested supernatants were obtained after milk fermentation with yogurt starter cultures either in co-culture with *L. harbinensis* K.V9.3.1Np (active supernatant) or not (control supernatant). Morphological changes (membrane collapsing and cell lysis) were observed in the target yeast. The authors attributed these effects to the synergistic action of

organic acids since 5 of the 8 organic acids quantified in the active supernatant (acetic, lactic, 2-pyrrolidone-5-carboxylic, hexanoic and 2-hydroxybenzoic acids) were at significantly higher concentrations than in the control one. These physiological mechanisms induced by an antifungal LAB could be used as part of the hurdle technology to prevent fungal spoilage in dairy products. On the other hand, Mosbah et al., (2018) studied the antifungal molecules produced by *Lb. harbinensis* K.V9.3.1Np when used in yogurt fermentation. Activity tests against *Penicillium* (*Pe.*) *expansum* and *Y. lipolytica* showed that the active compounds from this LAB-PC were benzoic acid and a polyamine identified as a spermine analog, which had not been reported earlier. Nevertheless, the highest activity was shown by a mixture of short polycyclic lactates.

Leyva Salas et al., (2017) found that, for a same antifungal LAB culture, a variable antifungal activity occurred between different semi-hard cheeses, suggesting a role of biotic and abiotic factors resulting from interactions between the food, the antifungal cultures and the fungal contaminants. The potential influencing factors could be the dry matter content in cheeses, ripening chamber humidity, interactions between the smear and the fungi, and non-sterility of the ripening chambers.

APPLICATIONS OF PROTECTIVE CULTURES IN MEAT PRODUCTS

Meat and meat products are perishable foods and they should be properly handled along the productive chain in order to prevent microbial growth. If spoilage microorganisms such as *Pseudomonas*, *Acinetobacter*, *Brochothrix thermosphacta*, *Moraxella*, *Enterobacter*, *Lactobacillus*, *Leuconostoc*, and *Proteus* are present and highly proliferated, the meat will spoil and will be unfit for human consumption (Jayasena & Jo, 2013). Additionally, pathogenic bacteria such as *Salmonella* spp., thermophilic *C. jejuni*, enterohemorrhagic *E. coli* O157:H7, *Clostridium* (*Cl.*) *perfringens*, anaerobic *Cl. botulinum*, *L. monocytogenes*, *S. aureus*, *B. cereus*, and *Ye. enterocolitica*, can be present in meat and meat products turning them hazardous for consumers (Hui, 2012). Therefore, assurance of meat safety and quality is of utmost importance. In this sense, LAB have been used as PC alone or in combination with several physicochemical treatments, modified atmosphere packaging (MAP), high hydrostatic pressure (HHP), and chemical preservatives, as an additional hurdle to control the proliferation of spoilage and pathogens microorganisms in meat and meat products. An endless variety of studies regarding LAB-PC application against target microorganisms on several meat products can be profoundly found in the literature (Castro et al., 2016, Castellano et al., 2017, Oliveira et al., 2018). Nevertheless, in this section the studies have been compiled with the selection criteria of up-to-date alternatives for meat biopreservation.

Several LAB species, including *Lactobacillus*, *Lactococcus*, *Pediococcus* and *Enterococcus* spp., have been evaluated to enhance microbial safety of meat and meat products due to their ability to produce bacteriocins active against *L. monocytogenes* (Oliveira et al., 2018, Woraprayote et al., 2016). As demonstrated by Giello et al., (2018), the use of the bacteriocin-producing *Lb. curvatus* 54M16 in fermented sausages could be an important contribution to improve the quality of final product. This strain produced several bacteriocins: sak X, sak T α , sak T β and sak P which are active against *L. monocytogenes*. The anti-listerial effect during the manufacture of fermented sausages naturally contaminated and co-

inoculated with a mixture of *L. monocytogenes* OH and Scott A (10^4 CFU/g) was investigated. Although this LAB-PC was partially effective in the control system against *L. monocytogenes* OH and Scott A, it was able to inhibit native *L. monocytogenes* over the course of the fermentation. Besides, *Lb. curvatus* 54M16 dominated and affected the bacterial ecosystem as it was determined by 16S rRNA-based analysis. It could be assumed that inoculated samples with PC helped on the dominance of *Lactobacillus* since un-inoculated sausages showed more diverse microbiota in which spoilage-associated bacteria, such as *Brochothrix*, *Psychrobacter*, *Pseudomonas* and some *Enterobacteriaceae*, were metabolically active until the end of the ripening.

Application of CO₂ modified atmosphere packaging in combination with antagonistic strain *Lb. plantarum* subsp. *plantarum* CICC 6257 as PC resulted in an effective strategy for enhancing microbiological safety of ground pork (Zhang et al., 2018a). The solely use of *Lb. plantarum* CICC 6257 had no significant effect on the lag-phase (λ) of *L. monocytogenes*, whereas its combination with CO₂ – MAP prolonged the λ and reduced the maximum specific growth rate ($\mu_{\max}$) and $N_{\max}$ of the pathogen in meat. The selected optimal treatment was the combined effect between *Lb. plantarum* CICC 6257 and 60% CO₂, by means of which the λ of *L. monocytogenes* increased from 3.43h to 8.33h, and the $N_{\max}$ and $\mu_{\max}$ were decreased by 46% and 66%, respectively.

Even though *Enterococcus* spp. are able to produce bacteriocins with strong anti-listerial activity (Khan et al., 2010; Gaaloul et al., 2015), safety aspects should be carefully assessed before their use as PC in meat and meat products since enterococci are known to be opportunistic pathogens causing several nosocomial infections (Rehaïem et al., 2014). In this sense, Ben Braïek et al., (2017, 2018) confirmed the innocuity of two *Ec. lactis* strains named Q1 (producer of enterocin P) and 4CP3 (producer of the enterocins A, B and P) to determine the effect of separate addition of these two strains in the control of *L. monocytogenes* in refrigerated chicken breast meat. These meat models were artificially contaminated with 10^5 CFU/g of *L. monocytogenes* and inoculated with each of the enterocin-producing *Ec. lactis* strains at a concentration of 10^7 CFU/g. In the presence of *Ec. lactis* Q1, viable populations of *L. monocytogenes* were reduced to 1.90 log CFU/g after 14 days, and then remained constant up to the end of the challenge experiment. While the addition of *Ec. lactis* 4CP3 caused a significant decrease of *Listeria* counts below the detection limit after 7 days and totally inhibited pathogen growth after 14 days of refrigerated storage (Ben Braïek et al., 2019). On the other hand, *Ec. mundtii* CRL 35 was found a promising strain to be used as a safe adjunct culture in sausage fermentation (Orihuel et al., 2018). This strain produces Enterocin CRL35, a pediocin like bacteriocin with anti-listerial and anti-viral activity (Salvucci et al., 2010; Wachsman et al., 2003). The effect of this PC on *L. monocytogenes* growth was evaluated in a meat model (beaker sausage) in the presence or absence of curing additives (NaCl, NaNO₂ and ascorbic acid). *L. monocytogenes* inhibition was enhanced when beaker sausage was supplemented with the curing mixture reaching a decrease greater than 2 log CFU/g. These results demonstrate that *Ec. mundtii* CRL 35 could be an efficient PC able to enhance hygienic quality of fermented sausages.

The effect of PC on other pathogenic microorganisms associated to meat and meat products has been also informed. *Cl. perfringens* strains have been implicated in outbreaks of food poisoning, particularly of meat and meat products (Grass et al., 2013). *Cl. perfringens* and its spores are supposed to grow or germinate under temperature abuse conditions, which commonly occur during the transportation, storage, or retail display of the meat chill chain. In

order to present a viable alternative for the control of *Cl. perfringens* on chicken breast meat, Li et al., (2017) investigated the effects of five LAB strains on *Cl. perfringens* growth, germination, and outgrowth of its spores under temperature abuse conditions. Among strain tested, *Lb. fermentum* R6 and *P. pentosaceus* P1, effectively inhibited the growth of vegetative cells and repressed germination and outgrowth of *Cl. perfringens* spores. However, the growth of *P. pentosaceus* P1 caused a deep decrease in pH values to 5.3 which made it not suitable as PC for this food matrix.

Ramaroson et al., (2018) selected LAB strains to be used as PC in cooked ham based on their antagonistic activity against pathogenic or spoilage spore-forming species as *B. cereus*, *Clostridium* sp. like *botulinum*, *Cl. frigidicarnis*, and *Cl. algidicarnis* and. Besides, the authors tested LAB-PC ability to resist High Pressure Processing (HPP). According to the results in model ham liquid medium, one *Lc. lactis* strain was selected because of its widest inhibitory spectrum, potential production of bacteriocin and ability to regrow following HPP. This PC could bring the opportunity of combining biopreservation and HPP to control spore-forming pathogens in cooked ham.

On the other hand, the combination of PC and chemical additives represents an alternative for the control of contaminants in meat environments, mainly enteric pathogens. Regarding this, Casquete et al., (2016) reported the efficacy of chitosan in combination with *P. acidilactici* bacteriocinogenic and non-bacteriocinogenic strains, in the control of *L. innocua*, *S. aureus*, *E. coli* and *Salmonella* Typhimurium in the fermented paste meat product Alheira (Portugal). Similarly, Hu et al., (2019) demonstrated that the combined use of chitosan and a bacteriocin-producing *Cb. maltaromaticum* strain reduced cell counts of *Salmonella* in lean beef.

The use of LAB as PC to inhibit growth of spoilage bacteria has been suggested by many authors (Hu et al., 2008; Jones et al., 2009; Biscola et al., 2014), and it is being considered as a strategy to improve the shelf life of meat and meat products. For instance, Zhang et al., (2018b) studied the bacterial diversity of vacuum-packaged sliced raw beef inoculated with the commercial cultures Bactoform B-2 (*Lb. sakei*) and SafePro B-LC-48 (*Lb. curvatus*) as PC by means of polymerase chain reaction-denaturing gradient gel electrophoresis (PCR-DGGE). The DGGE profiles of DNA extracted from non-inoculated samples showed that *Enterobacteriaceae* and *Pseudomonas fragi* emerged early, then *Brochothrix thermosphacta* shared the dominant position, and finally, *Ps. putida* showed up to become predominant. The addition of either *Lb. sakei* or *Lb. curvatus* reduced the complexity of microbial diversity and inhibited the growth of spoilage bacteria with *Lb. sakei* exerting greater inhibitory effect. In other study, Comi et al., (2016) examined the use of the strains *Lb. sakei* (B-2 Safe Pro® e CHR HANSEN) and *Lc. lactis* subsp. *lactis* (Rubis e CHR HANSEN) as PC to reduce the risk of *Leuconostoc* (*Leuc*) *mesenteroides* spoilage in artisanal cooked bacon. LAB strains were inoculated on pieces of bacon together with a mix of three different *Leuc. mesenteroides* strains isolated from spoiled cooked bacon and responsible for the greening color and spoilage. After 90 days of storage, sticky-white slime and a greening color were observed in the cooked bacon inoculated only with *Leuc. mesenteroides*. While cooked bacon with PC did not present greening, slime or inflated packaging. At this stage of the storage, the ratios *Leuc. mesenteroides*/*Lc. lactis* subsp. *lactis* and *Leuc. mesenteroides*/*Lb. sakei* were about 1/100 and 1/1000, respectively. Based on these results, the authors assumed that substrate competition by PC was responsible for *Leuc. mesenteroides* growth inhibition, thus suppressing its spoilage effects. Moreover, the acceptability of the bacon added with PC was

confirmed with sensorial analysis. These results illustrate the benefits of inoculation with LAB, especially *Lb. sakei* as a potential way to inhibit growth of spoilage microorganisms and to prolong the shelf life of meat and meat products.

APPLICATIONS OF PROTECTIVE CULTURES IN FRESH SEAFOOD AND SEAFOOD PRODUCTS

Fish is a very delicate product since its shelf life is remarkably short due to autolytic reactions and microbial proliferation. Autolytic reactions involve the action of proteases that generate an increase of free amino acids and free volatile bases (Huss, 1995), which allow microbial growth to be faster than in other types of meat. Main deteriorative strains present in fish include Gram negative microorganisms such as *Shewanella* sp., *Aeromonas* sp., *Pseudomonas* sp., *Photobacterium* sp., Enterobacteriaceae and some Gram positive bacteria such as LAB, including *Carnobacterium* sp., and *Lactobacillus* sp. (Cifuentes Bachmann & Leroy, 2015). Main pathogenic bacteria responsible for fish poisoning are *Aeromonas hydrophila*, *Cl. botulinum*, pathogenic *Vibrio* spp. and *L. monocytogenes* (Løvda, 2015). Additionally, fatty fish lipid composition is characterized for a high proportion of polyunsaturated fatty acids, which are highly oxidable, and thus, nutritional value is lost at very fast rates. Furthermore, after fish is captured in coastal areas, it is firstly stored at fishing boats, and then distributed to non-coastal areas, so a long period of time passes before fish products reach consumers (Wiernasz et al., 2017). All these characteristics make fish an important vector for food-borne diseases, yielding between a 10% and a 20% of total food borne diseases worldly (Pilet & Leloir, 2011).

In the last years LAB have been widely studied to be used on fish preservation. Even though their main action is usually against Gram positive microorganisms, -as an extra hurdle, they contributed to control native fish flora and specifically to control *L. monocytogenes* growth. Additional hurdles in fish preservation include modified atmosphere package, vacuum package, addition of essential oils, plant extracts, refrigeration, addition of active films, marinade and diminishment of water activity (Boulares et al., 2016; Concha-Meyer et al., , 2010; López de Lacey, López-Caballero, & Montero, 2013; Sarika et al., 2012).

LAB have been added to fish products in different manners: as PC, as bacteriocins purified or semi purified, and either LAB or bacteriocins immobilized in different films or coatings. Regarding the application as protective culture, LAB may produce bacteriocins *in situ* and compete with native fish bacteria, generating a bacteriostatic effect as well as a bactericidal one. Limitations to these applications may include the generation of off flavors (Saraoui et al., 2017) and the difficulty of LAB to grow and produce bacteriocins *in situ*. To partially overcome LAB *in situ* lack of activity, antagonist activity may be tested in fish juice (Wiernasz et al., 2017), to get a more accurate prediction of LAB activity when applied to fish products. When purified or semi-purified bacteriocins are applied directly to fish, issues related to cell viability are bypassed, but it is necessary to foresee a bacteriocin concentration capable to maintain a threshold concentration at which native flora would stay inhibited, since bacteriocin concentration may be affected by lytic action of proteolytic bacteria (Giribaldi et al., 2018). Finally, when immobilizing bacteriocins, their structure may be protected, and

their release modulated (Settier-Ramírez et al., 2018). When LAB are immobilized, they may be released in a controlled manner to food, thus preventing them from overgrowing and acidifying. Anyhow, immobilization must ensure cell viability and bacteriocin bonding in a manner that would not affect their antagonist action.

Comparing some of the aforementioned preservation techniques, Gómez-Sala et al., (2016) evaluated the use of *Lb. curvatus* BCS35 and *Ec. faecium* BNM58 on young hake and megrim, both applied as PC, liquid food ingredient or lyophilized food ingredient. In this case, when strains were used as PC the best results were achieved: coliform population was diminished throughout 14 days of storage, as well as the total mesophilic count, and fish appearance was improved, compared to control system. Boulares et al., (2016), added *Lb. plantarum* and *Cb. piscicola* and *Lc. lactis* as PC to sea bass, and found an improvement on fatty acid composition, and protein profile, indicating that the use of both LAB could control both proteolytic and lipolytic activities of deteriorative native bacteria. Their study also showed that the best combinations to control the growth of *Listeria* spp. population were mixtures of *Lc. lactis*-*Lb. plantarum* and *Lc. lactis*-*Cb. piscicola*, and a mixture of *Lb. plantarum*-*Cb. piscicola*, which was the best to control total basic volatile nitrogen and trimethylamine. Co-cultures had also been capable of diminishing undesired off-flavors generated by very active bacteriocinogenic strains, which by itself could not be applied to fish products. Such is the example of a co-culture of *Lc. piscium* and *Cb. divergens* since the addition of *Lc. piscium* inhibited the production of off flavors produced by *Cb. divergens* in shrimp preservation, extending their shelf life for 10 extra days in comparison to shrimps only inoculated with *Cb. divergens* (Saraoui et al., 2016). From these studies it may be concluded that the use of LAB strains may control different aspects of fish deterioration, and that there is a strong dependence on strain mixture.

The application of LAB cell free supernatant (CFS), purified or semi purified bacteriocins has also been assessed on fish preservation. The most used purified bacteriocin has been nisin in combination with extra hurdles. Novel applications of nisin include the addition of the bacteriocin in alginate films. Concha-Meyer et al., (2010), applied nisin together with two different LAB strains of *Cb. maltaromaticum*, to prolong shelf life of smoked salmon, and analyzed the anti-*Listeria* effect on samples. Systems containing nisin alone, or together with both LAB strains, showed a bacteriostatic effect on *L. monocytogenes*; in addition, in systems inoculated with both LAB, there was a decrease of the pathogens on day 28, due to the release of the bacteriocinogenic strains into the salmon filets. Lu et al., (2009), managed to increase the shelf life of northern sea snake filets by adding nisin together with EDTA, mixed or not on a calcium alginate film. Their results showed that the coating did not improve overall quality indicators (total mesophilic and psychrophilic bacterial counts, TBV-N, TMA-N, pH, or TBA) compared to samples only sprayed with the antimicrobials. Still, all treated samples showed values below maximum allowed for fish products throughout the storage, indicating that the mixture of nisin and EDTA had a positive effect on fish shelf-life. Nevertheless, sensory characteristics were improved by the application of the preservatives together with the alginate coating. These results showed that coatings are a promising technique to use on fish preservation, but factors such as release speed of antimicrobials (related to calcium-alginate concentration) should be further studied (Fang & Tsai, 2003).

Biopreservation of fish, has also been used together with other naturally occurring additives such as plant extracts, since they have been informed to have antagonist activity

against Gram negative microorganisms (Djeussi et al., 2013), and their richness in polyphenols and components with antioxidant activity may favor fish preservation. López de Lacey, López-Caballero, & Montero (2013) used a bioactive film prepared with agar in addition with green tea and *Lb. paracasei* L26 and *Bifidobacterium lactis* B94, obtaining a shelf life extension of hake fillets for 7 extra days (14 days in total). This study also showed that the probiotic strains could migrate from the film to the fillets increasing their population. It is important to highlight that the green tea extract did not affect the viability of inoculated bacteria, but diminished the presence of native LAB on samples. Dos Reis et al., (2011) investigated the synergic action of two different strains of *Cb. maltaromaticum* cultures and hydroalcoholic extract of *Lippia sidoides* (LSE) on fish food models: surubim fish peptone broth and surubim homogenate. In this case, *Cb. maltaromaticum* by itself did not control the growth of *L. monocytogenes*, neither did the LSE, but a synergic activity of both antimicrobial factors was found, and the pathogen population was controlled for 28 days on fish homogenate.

LAB can be used as an extra hurdle together with other preservation techniques which require LAB to grow under refrigeration, without the presence of oxygen as well as under low water activity conditions. Giribaldi et al., (2018) obtained an improvement on swordfish fillets fatty acid profile, for 60 days, on ready to eat fillets treated with marinade water solution containing 3% NaCl for 2 days together with an immersion on a probiotic culture of *Lb. paracasei* IMPC 2.1. Tomé, Gibbs, & Teixeira (2007) used another preservation technique (dry salted for 6 hours; drying for 6 hours; smoking for 2 hours), and compared the biopreservation capacity of 5 LAB (*Enterococcus faecium* ET05, *Lb. curvatus* ET06, *Lb. curvatus* ET30, *Lb. delbrueckii* ET32 and *Ped. acidilactici* ET34) on salmon. After 21 days of storage at 5°C, the growth of *L. innocua* 2030c was best controlled by the strain *E. faecium* ET05, achieving a reduction of 5 log UFC at the end of storage in comparison to control samples.

PROTECTIVE CULTURES IN THE BIOPRESERVATION OF FRUITS, VEGETABLES AND MISCELLANEOUS FOOD PRODUCTS

Fruits and Vegetables

Fruits and vegetables are highly perishable foods. Their deterioration is the result of biochemical changes, physiological ageing and microbial spoilage. Most of the bacteria causing the spoilage of fruits and vegetables are Gram-negative and belong to the genera *Pseudomonas* and *Enterobacteriaceae*. Within the present Gram-positive bacteria, it is usual to detect LAB. Regarding pathogenic microorganisms, fruits and vegetables may harbor *L. monocytogenes*, *Salmonella* spp. and *Escherichia coli* O157:H7. Finally, fungi and yeasts could also be found, which cause the deterioration of these foods although to a minor proportion than bacteria (Rico et al., 2007; Oliveira et al., 2015).

Taking into account the risks to consumer health and the economic losses that microorganisms' proliferation in fruits and vegetables may cause, the application of some preserving methods is necessary. However, in this type of food it is extremely important to maintain its condition of "fresh" or "minimally processed," being inconvenient to use severe

methodologies. In this context, the combination of various emerging preservation technologies is presented as a possible solution. Among them, the use of PC or the bacteriocins produced by them is outstanding. While the biopreservation of fruits and vegetables has not been studied as well as the biopreservation of other types of foods, there are numerous reports regarding its effect on these matrices and some of them are summarized in Table 1.

Regarding minimally processed fruits, a large amount of investigations has focused on isolating native LAB showing inhibitory activity against the deteriorative or pathogenic microorganisms usually found in these products. For example, Siroli et al., (2015) isolated native LAB from sliced apples and reported that, among the isolates with inhibitory activity against *L. monocytogenes*, *Salmonella enteritidis* E5 and *E. coli* 555, the strains identified as *Lb. plantarum* CIT3 and *Lb. paracasei* M3B6 were the most notable. The latter significantly decreased the population of *L. monocytogenes* and *E. coli* in minimally processed apples. In addition, when *Lb. plantarum* CIT3 was combined with natural antimicrobials the observed effect was greater. In a similarly targeted study, Siroli et al., (2016) evaluated the application of *Lc. lactis* CBM21, alone or in combination with natural antimicrobials, as PC in sliced apples. The authors reported that the use of *Lc. lactis* limited the growth of yeast and inhibited the development of *L. monocytogenes*. The effectiveness of the PC in controlling the growth of *L. monocytogenes* was attributed to the ability of the former to produce nisin. It should be noted that the inhibitory effect was greater when the PC was combined with natural antimicrobials.

Probiotic fortification has been extensively studied to produce foods with functional properties. Regularly, dairy products are more prone to be labelled as functional foods; however, probiotic fruits and vegetables could provide a good alternative for vegetarian or vegan consumers. In addition to beneficial effects on the health of consumers, some probiotic microorganisms can act as PC. Russo et al., (2015) studied the capability of *Lb. plantarum* B2 and *Lb. fermentum* PBCC11.5 to control the growth of *L. monocytogenes* in refrigerated melon and found that the 2 PC showed antagonistic activity against the pathogen. Furthermore, Iglesias et al., (2018) reported that the probiotic *Lb. rhamnosus* GG inhibited the growth of *L. monocytogenes* on fresh-cut pear but did not show antagonistic action against *Salmonella*.

In products derived from fruits, such as juices, the application of PC has not been widely studied. However, the application of bacteriocins has proved to be very effective. *Alicyclobacillus acidoterrestris* is a spoilage-causing bacterium in fruit juices. The addition of different bacteriocins, for example enterocin AS-48, nisin or bificin C6165, produced the inhibition of this microorganism and in some cases inactivated its endospores (Grande et al., 2005; Walker & Phillips, 2008; Pei et al., 2014).

The use of native flora to control microbial growth was also studied in vegetables. Siroli et al., (2015) isolated LAB from lamb lettuce and selected *Lb. plantarum* V7B3 and *Lb. casei* V4B4 as potential biocontrol agents for minimal processed lamb lettuce. Both PC were able to inhibit the growth of *L. monocytogenes* and *E. coli*, and also reduced the population of aerobic mesophilic microorganisms. Seemingly to the aforementioned application on apples, the combination of the PC with natural antimicrobials improved the biopreservation results. In another study using the same raw matrix, Siroli et al., (2017) compared the effectiveness of different washing solutions for lettuce. For this purpose, the samples were washed with: i) chlorine 120 mg/L, ii) thyme essential oil 250 mg/L, iii) *Lc. lactis* CBM21 10^6 CFU/ml, iv)

thyme essential oil and *Lc. lactis* CBM21. The results showed no differences between the populations of microorganisms in the different systems. In addition, the sensory characteristics of the samples washed with thyme essential oil and *Lc. lactis* CBM21 were superior.

Moreover, Trias et al., (2008) studied the effect of 3 strains of *Leuc. mesenteriodes* (CM135, CM160 and PM249), previously isolated from fresh fruits and vegetables, on the development of *L. monocytogenes* in Iceberg lettuce. Before being applied to vegetables, the 3 strains were characterized and it was found that 2 of them (CM135 and CM160) produced bacteriocins with antagonistic activity against *L. monocytogenes* and against other LAB. When inoculating the lettuce with 10^9 CFU/g of *Leuc. mesenteriodes*, no development of *L. monocytogenes* was detected. However, as the concentration of PC decreased, the inhibitory effect also declined. The application of these 3 strains to fresh fruits and vegetables did not cause sensory changes.

As mentioned above, the deterioration of vegetables may be a consequence of the development of fungi and yeasts. In this context, Sathe et al., (2007) isolated LAB from different vegetables and studied their antifungal activity. Among the isolated strains, *Lb. plantarum* CUK-501 showed antifungal activity against all the indicators studied *in vitro*. For *in vivo* studies, *Lb. plantarum* was inoculated into cucumber. Results showed that *Aspergillus flavus*, *Fusarium graminearum*, *Rhizopus stolonifer* and *Botrytis cinerea* growths were delayed. Similar results were found when the PC was replaced by the CFS.

As well as fruit juices, the use of PC has not been studied in canned vegetables. However, studies were carried out applying bacteriocins. Lucas et al., (2006) studied the antimicrobial activity of the enterocin AS-48 against *B. coagulans* in canned vegetables. After 24 hours of storage at different temperatures, the enterocin AS-48 reduced *B. coagulans* population, and after 15 days of storage, no viable cells were detected. In addition, the enterocin AS-48 increased the thermal sensitivity of *B. coagulans* spores.

Finally, lactic acid fermentation of vegetables should not be omitted. This technology has historically been used in many cultures as an effective method of food preparation and preservation. Lactic acid fermentation is a simple and valuable biotechnological tool to maintain and/or improve the safety, nutritional, sensory and preservation properties of fruits and vegetables (Di Cagno et al., 2013). In general, the starters cultures are selected because of their technological potential, such as the production of acid or exopolysaccharides. However, their antimicrobial activity should not be ignored (Settanni & Corsetti, 2008). For example, Di Cagno (2008) isolated autochthonous microorganisms (*Ln. mesenteroides* C1, *Lb. plantarum* M1 and *Ped. pentosaceus* C4) from carrots, French beans and marrows, and applied them as fermentation starters for the same vegetables. In addition to the good sensory characteristics, the authors found that the starters were able to inhibit the growth of *Enterobacteriaceae* and yeasts.

Considering the topics discussed, it can be concluded that the use of PC and bacteriocins plays a determining role in the control of deteriorative and pathogenic flora of fruits and vegetables. However, in both cases, they should always be applied within the context of hurdle technology, since their spectrum of action is reduced. In addition, it is important to note that each strain used as PC must be tested on the food to be applied and against a broad spectrum of indicator microorganisms.

Miscellaneous Food Products

Bioprotective cultures are also used to preserve a diverse kind of food products such as different beverages and bakery products. Bakery products are prone to post-treatment contamination by mold spores. Fungal development conducts to mycotoxin production and sensory spoilage which limit shelf life and causes significant health and economic losses. To overcome this issue, the search for bioprotective cultures exhibiting antifungal activity has gained interest in the last years as an alternative to chemical preservatives. Furthermore, some LAB also exhibited antimycotoxin properties (Guimarães et al., 2018; Juodeikiene et al., 2018). Le Lay et al., (2016) isolated several strains for the species *Leuc. citreum*, *Lb. sakei*, *Lb. plantarum*, *Lb. spicheri*, *Lb. reuteri* and *Lb. brevis* which were able to delay fungal growth by surface spraying to bakery products. Furthermore, some of these protective cultures led to delay fungal growths after incorporation in milk bread rolls preparation. Cizeikiene et al., (2013) used a spray containing a mixture of *Ped. acidilactici* KTU05-7, *Ped. pentosaceus* KTU05-8 and KTU05-10 strains that produce organic acid and bacteriocin like inhibitory substances to suppress superficial mold development on bread for 8 days of storage at 15°C in polyethylene bags. Trends commented suggest that bioprotective cultures can be used for controlling molds in bakery products.

Guimarães et al., (2018) selected the strain *Lb. plantarum* UM55 among different LAB due to its ability for inhibiting the growth of *Aspergillus (A.) flavus*. Furthermore, the cell-free supernatant (CFS) of this strain was able to inhibit by 91 % the production of aflatoxins (AFLs). It had also inhibited the growth and AFLs production of *A. parasiticus*, *A. arachidicola*, *A. nomius* and *A. minisclerotigenes*. This antimycotoxyn activity was due to the presence of phenyllactic acid, hydroxyphenyllactic acid, and indole lactic acid, being phenyllactic acid the one that exerted the stronger effect. Similar results were found by Schmidt et al., (2018) who reported that *Lb. reuteri* R29 exhibited a broad spectrum of antifungal activity due to the presence of phenyllactic acid. Based on mentioned trends, Bustos et al., (2018) using a factorial design optimized a low-cost medium to obtain biomass and phenyllactic acid production by *Ped. acidilactici* CRL 1753 strain. Furthermore, this strain was proposed to be used as a biopreservative in bread making to increase the shelf life of wheat bread.

Although is it known that nisin producer strains could prevent malolactic fermentation in wines and also they may serve to reduce the amount of sulfur dioxide, their use in winemaking to control bacterial spoilage (Daeschel et al., 1991) was evaluated only recently. Fernández-Perez et al., (2018) assessed the use of *Lc. lactis* LM29 under enological conditions to decrease sulfur dioxide addition. Results showed that this lactococci strain was able to produce nisin in the presence of 2 and 4% ethanol (v/v), while higher concentrations of ethanol fully inhibited bacteriocin production. Furthermore, the use of 50 mg/L nisin as additive decreased fourfold the concentration of sulfur dioxide required to prevent LAB growth during wine ageing.

CONCLUSION

Taking into consideration the abundant advantages of LAB strains, their potentiality as PC or biopreservatives is undeniably, providing therapeutic value to fermented food products, contributing to public health and reducing economic losses related to spoilage. Since fermented foods are consumed daily by people, the proper selection of protective cultures with different beneficial properties to enhance safety and promote health is a need within novel and reliable methods for food preservation.

Chapter 293

THERMOTOLERANT PROBIOTIC LACTIC ACID BACTERIA IN COOKED MEAT PRODUCTS

M. L. Pérez-Chabela*

Biotechnology Department, Universidad Autónoma Metropolitana,
Iztapalapa, Alcaldía de Iztapalapa, México City, Mexico

ABSTRACT

Lactic acid bacteria are part of the native flora in fresh meat, but certain strains have been employed as starter cultures in fermented meat products, becoming dominant flora due to lactic acid production, and a natural preservative. Nonetheless, although lactic acid bacteria are mesophilic, they cannot be employed as starter cultures in cooked meat products due to their limited survival to thermal processes. However, certain lactic acid bacteria isolated from cooked meats present the characteristics of thermotolerance, i.e., they survive thermal processes above 70°C for at least 30 min. These bacteria can overexpress heat shock proteins that are produced in response to exposure to a stressful environment, such as temperature or pH. These thermotolerant lactic acid bacteria present probiotic characteristics: being able to survive gastric tract conditions to colonize the small intestine and cell adhesion capacity. In addition, inoculation of these lactic acid bacteria in on cooked meat batters has no detrimental effect on texture, yield, color and sensory acceptance. The probiotication of cooked and emulsified meat products can be achieved with thermotolerant probiotic lactic acid bacteria.

INTRODUCTION

Lactic acid bacteria (LAB) are a group of Gram-positive bacteria, nonsporing cocci or rods, which produce lactic acid as the major end product of the fermentation of carbohydrates (Axelsson, 2004). They have a low content of GC, tolerate acidic conditions, are immobile, nutritionally demanding and must be administered vitamins, amino acids, purines and

* Corresponding Author's Email: lpch@xanum.uam.mx.

pyrimidines, lack catalase and facultative anaerobes, but are sometimes classified as aerotolerant anaerobes (Willey et al., 2008). They are found in dairy products, meat products and the human body, and are classified as GRAS (generally recognized as safe).

Lactic acid bacteria are divided into homolactic and heterolactic fermentative. Homolactic fermentation (Glycolysis Embden-Meyerhof-Parnas pathways) results almost exclusively in lactic acid as the end product, and heterolactic fermentation (the 6-phosphogluconate/phosphoketolase pathways) results in significant amounts of other end products, such as acetate, ethanol, CO₂ and lactic acid (Axelsson, 2004).

The LAB considered natural strains in meat and meat products are *Carnobacterium piscicola*, *Carnobacterium divergens*, *Lactobacillus sakei*, *Lactobacillus curvatus*, *Lactobacillus plantarum*, *Leuconostoc mesenteroides*, *Leuconostoc gelidum* and *Leuconostoc carnosum* (Hugas, 1998). LAB are employed as starter cultures in non-thermal processed fermented meat products, such as salami, but can easily grow at refrigeration temperatures, although they are considered mesophilic.

In this chapter, probiotic characteristics of thermotolerant LAB such as the survival in the gastrointestinal tract, the colonization of the intestine and cell adhesion capacity of thermotolerant lactic acid bacteria will be presented. In addition the inoculation of these LAB on cooked meat batters will be discussed.

THERMOTOLERANCE

Thermal tolerance or thermotolerance has been defined as the ability of an organism and of its cell structures to withstand (survive) destructive heat stress exceeding the range of optimal temperature for its development (Parsell and Lindquist, 1993). Mammalian cells can dramatically increase their tolerance to thermal damage after prior heat conditioning. The evidence suggested that heat shock proteins (HSP) provide the protective mechanism (Burdon, 1987).

Heat Shock Proteins. Classification

The first to publish the observation that cells could mount very strong transcriptional activity when exposed to elevated temperatures was Ritossa (1962), being coined the heat shock response. This discovery led to the identification of heat shock proteins.

Heat shock proteins (HSPs), or stress proteins, are present in all organisms and in all of their cells. Selected HSPs, also known as chaperones, play crucial roles in folding/unfolding of proteins, assembly of multiprotein complexes, transport/sorting of proteins into correct subcellular compartments, cell-cycle control and signaling, and protection of cells against stress/apoptosis (Li & Srivastava, 2003).

HSPs are broadly classified by molecular weight into distinct families: Hsp100, Hsp90, Hsp70, Hsp60, Hsp40, small Hsp and Hsp10 (Richa et al., 2007). The functions of the Hsp are acting like chaperones to maintain and control protein and proteases native structure. All HSP families possess chaperone activity (Sikora & Grzesiuk, 2007). Many members are

present constitutively in cells while some are only expressed after stress. Table 1 shows the HSP Family, localization and functions.

Table 1. HSP Family, localization and function in the tissue

Family	Localization	Function	Reference
Hsp100	Cytosol	Chaperones	Mogk et al., 2015
Hsp90	Cytosol	Chaperones	Pearl & Prodromou, 2006
Hsp70	Cytosol	Chaperones	Schuermann et al., 2008
Hsp60	Mitochondria, cytosol and nucleus	ATP-dependent chaperone	Okamoto et al., 2017.
Hsp40	Nervous system	Co-chaperones	Gorenberg & Chandra, 2017
sHsp	Ubiquitous, heart, muscle, placenta, cytoplasm.	Chaperones	Bakthisaran et al., 2015; Garrido et al., 2012.
Hsp10	Mitochondria, cytosol	Co-chaperones	Fan et al., 2017; Jia et al., 2011.

Hsp100

The Hsp100 family of molecular chaperones shows a unique capability to resolubilize and reactivate aggregated proteins. The Hsp100-mediated protein disaggregation is linked to the activity of other chaperones from the Hsp70 and Hsp40 families. The best studied members of the Hsp100 family are the bacterial ClpB and Hsp104 from yeast. Hsp100 chaperones are members of a large super-family known as AAA+ ATPases (Zolkiewski et al., 2012). The AAA (ATPases associated with various cellular activities) family is a large group of ATPases found in all biological kingdoms and characterized by the presence of one or two conserved ATP-binding domains of a type called the AAA motif. This 200–250 amino-acid domain is defined by sequence and structural properties (Bar-Nun & Glickman, 2012).

The Hsp100 forms a bi-chaperone system composed of ATP-dependent Hsp70 and hexameric Hsp100 (ClpB/Hsp104) chaperones, which rescues aggregated proteins and provides thermotolerance to cells (Mogk et al., 2015).

Hsp90

The 90 kDa heat shock proteins are a family of molecular chaperones found in bacteria and all eukaryotes, but are absent in archaea. Many eukaryotes possess multiple Hsp90 homologues, including endoplasmic reticulum and mitochondrial isoforms (Pearl & Prodromou, 2006). The Hsp90 chaperone family includes the eponymous Hsp90 (90 kDa heat shock protein) of the eukaryotic cytosol, termed variously Hsp90 α and β in humans (corresponding to a major and minor isoform), Hsp86 and Hsp84 in mice, Hsp83 in *Drosophila*, and Hsc82 and Hsp82 in yeasts. Other family members are HtpG in the bacterial cytosol, Grp94/gp96 in the endoplasmic reticulum of eukaryotes, and the Hsp75/TRAP1 in the mitochondrial matrix (Young et al., 2001).

The Hsp90 is a key regulator of proteostasis under both physiological and stress conditions in eukaryotic cells. As Hsp90 has several hundred protein substrates (or “clients”), it is involved in many cellular processes beyond protein folding, which include DNA repair, development of the immune response and neurodegenerative disease. Owing to the importance of Hsp90 in the regulation of many cellular proteins, it has become a promising drug target for the treatment of several diseases, which include cancer and diseases associated with protein misfolding (Schopf et al., 2017).

Hsp70

Hsp70s are a diverse family of chaperones involved in a variety of protein processing reactions, including import into the endoplasmic reticulum and mitochondrion, protein folding, and the remodeling of protein complexes (Schuermann et al., 2008). Hsp70 has two isoforms of 66 and 76 kDa, both called Hsp70, which is derived from a gene with the same name (Evans et al., 2010). HSPs prevent incorrect folding. Hsp70 plays a role in folding of proteins that have been destroyed and damaged by stress. The most important roles of Hsp70 are the management of folding of damaged and abnormal proteins (Valizadeh et al., 2017).

Hsp60

The eukaryotic heat shock protein Hsp60 (GroEL) belongs to the group I of chaperonins and is classically defined as an intramitochondrial protein that assists with the correct folding of other mitochondrial proteins, together with its co-chaperonin Hsp10 (GroES) (Bukau & Horwich, 1998).

Hsp60 plays an essential role in protein homeostasis through mediating protein folding and assembly. It was found that Hsp60 has different properties with respect to allostery, complex formation and protein folding activity, depending on the nucleoside triphosphate present (Okamoto *et al.*, 2017). Since the initial discovery of Hsp60 as the mitochondrial molecular chaperone many studies have shown that it is also localized outside mitochondria with perhaps both chaperoning and non-chaperoning activities. Therefore, it is not surprising that many different disease states, especially autoimmune diseases and cancers, have presented altered expression levels of Hsp60 (Meng et al., 2018). Recent investigations have suggested that Hsp60 functions and interactors may vary, depending on its cell and tissue localization, giving this protein the capacity to be a multifaceted molecule in the middle of the delicate balance between health and disease (Marino et al., 2018).

Hsp40

Ohtsuka et al., (1990) discovered a novel 40-kDa protein in addition to the classical heat shock proteins with molecular sizes of 110-, 90-, 70-, and 47-kDa. The p40 was induced not only by heat shock but also by arsenite and 2-azetidine carboxylic acid. It was induced in rat, mouse and chicken cells by these stresses. The p40 is a novel heat shock protein in mammalian and avian cells.

Heat shock proteins also called DnaJ/Hsp40 proteins have been preserved throughout evolution and are important for protein translation, folding, unfolding, translocation, and degradation, primarily by stimulating the ATPase activity of chaperone proteins, Hsp70s. DnaJ/Hsp40 proteins actually determine the activity of Hsp70s by stabilizing their interaction with substrate proteins (Qiu et al., 2006). Hsp40s are defined by their conserved J domain and typically have large variation in the rest of the protein. Classical Hsp40s have both a J domain as well as a zinc finger domain that regulates client protein binding. The J domain of Hsp40 proteins consists of a 70-amino acid sequence with four alpha helices (Gorenberg & Chandra, 2017).

sHsp

Small heat shock proteins (sHsp) were discovered in *Drosophila melanogaster* salivary glands as a set of sHsp, with small molecular weight (15–30 kDa) induced after a heat shock and accumulating in the cells after many different environmental, physiological or pathological stresses (Tissieres et al., 1974). The human sHsp family contains ten members and one related protein (HSP16.2/HSPB11) is ubiquitously expressed while others are only expressed in specific tissues (Garrido et al., 2012).

Small heat shock proteins (sHsps) are conserved across species and are important in stress tolerance. Many sHsps exhibit chaperone-like activity in preventing aggregation of target proteins (Bakthisaran et al., 2015). The sHsp participate in a large number of fundamental cellular processes such as controlling protein folding, F-actin-dependent processes, cytoprotection/anti-apoptosis, differentiation, cell proliferation, and gene expression, and therefore are involved in many pathologies, such as neurodegenerative diseases, cancer, and cardiovascular diseases (Guo & Wu, 2015).

Hsp10

Protein folding in mitochondria is mediated by the chaperonin Hsp60, the homologue of *E. coli* GroEL. Mitochondria also contain a homologue of the cochaperonin GroES, called Hsp10. Hsp10 is required for the folding and assembly of proteins imported into the matrix compartment, and is involved in the sorting of certain proteins, such as the Rieske Fe/S protein, passing through the matrix en route to the intermembrane space (Hohfeld & Ulrich, 1994).

Hsp10, an important member of Hsps family, classically works as a molecular chaperone folding or degradating of target proteins. Evolutionarily, Hsp10 is also reported to be involved in immunomodulation and tumor progression (Fan et al., 2017). Hsp10 appears to be related to pregnancy, cancer and autoimmune inhibition. It can be released to peripheral blood at a very early time point of pregnancy and received another name, early pregnancy factor (EPF), which seems to play a critical role in developing a pregnant niche (Jia et al., 2011).

HSP IN LACTIC ACID BACTERIA

LAB are important starter, commensal, or pathogenic microorganisms. The stress physiology of LAB has been studied in depth for over 2 decades, fueled mostly by the technological implications of LAB in the food industry (Papadimitriou et al., 2016).

Hartke et al., (1996) studied the lactic acid tolerance of *Lactococcus lactis* subsp. *lactis*. The results showed a dramatic increase in survival to severe acid stress during 30 min at pH 3.9. One protein extract analysis revealed that the major heat shock proteins DnaK and GroEL are produced during acid tolerance. Highly conserved chaperones, DnaK, DnaJ, GrpE, GroES, GroEL, and proteases Clp, HtrA, and FtsH, have been detected in LAB (Guchte et al., 2002). Lactobacilli respond to stress in specific ways dependent on the strain, species, and the type of stress.

Coucheney et al., (2005) studied the *Oenococcus (O.) oeni*, a lactic acid bacterium mostly responsible for malolactic fermentation in wine. This bacterium produces an 18 kDa sHSP, called Lo18 that is induced by multiple stresses, such as heat, ethanol, sulphites, and low pH,

among others. *O. oeni* cells showed that purified Lo18 interacts with the liposomes and increases the molecular order of the lipid bilayer in these membranes when the temperature reaches 33.8°C. These data suggest that Lo18 could be involved in an adaptive response allowing the maintenance of membrane integrity during stress conditions in *O. oeni* cells.

Spano et al., (2005) using a molecular approach based on PCR, RT-PCR and Northern blot analysis, described a new member of the small heat shock family of wine, *Lactobacillus (Lb.) plantarum*. The protein had a calculated molecular of mass of 18.548 kDa and was named Hsp18.55. Expression of the newly identified small heat shock gene was induced by a wide range of abiotic stresses including heat, cold and ethanol, suggesting that the small family of heat shock genes is probably involved in the general stress response in *Lb. plantarum* from wine.

Capozzi et al., (2011) studied the *Lb. acidophilus* hps16 gene structure, genomic organization, and deduced amino acid sequence. The results indicated a strong evolutionary relationship within members of the *Lb. acidophilus* group. This species is used to drive dairy fermentations and in functional probiotic foods and is therefore commonly exposed to multiple physiological stresses. Wu et al., (2014) reported that a small heat shock protein (18 kDa) probably indicated the link between the osmotic tolerance of *Lb. paracasei* during fermentation due to salt stress response.

Pandi and Basher (2016) studied the stress resistance of *Lactobacillus* strains and concluded that the genus *Lactobacillus* contains many stress resistant organisms. They can produce stress resistant metabolites like trehalose and heat shock proteins during growth at high temperatures, which helps the growth of microorganisms at high temperatures. Serata et al., (2016) reported Hsp18 and GroEL as one gene involved in oxidative stress resistance in *Lb. casei* strain Shirota.

Wang et al., (2017) studied the characteristics of four isolated LAB and their effects on fermentation quality of Italian ryegrass (*Lolium multiflorum* Lam.), which is difficult to silage on the Tibetan Plateau due to the low temperature. The results showed that *Lb. plantarum* strains overproducing Hsp 18.5, Hsp 18.55, and Hsp 19.3 can grow better at low temperatures.

THERMOTOLERANT LACTIC ACID BACTERIA IN MEAT PRODUCTS

The three-dimensional structure of cellular proteins is sensitive to small increases when they are exposed to high temperature, and the misfolding and aggregation of unfolded proteins are the primary problems for cells subjected to heat stress (Varmanen and Savijoki, 2011).

LAB are employed as starter cultures for the fermentation of meat products. In some countries, cooked meat products undergo a heat treatment of 70°C (pasteurization temperature) in their processing; some LAB can survive this treatment due to the production of Hsp.

The role of LAB in both cooked and fresh meat products is controversial due to the spoilage characteristic of LAB. On one hand, several species are able to dominate the meat system in VP and MAP storage conditions and can release odor-impact molecules, which may alter the sensory profile of raw or cooked meat. On the other hand, LAB have a bioprotective

function since they can provide favorable antagonistic activity against other undesired microorganisms (Pothakos et al., 2015).

Chenoll et al., (2006) analysed the presence of LAB associated with a variety of vacuum-packed fresh and spoiled meat products. From a total of 18 samples, *Lactobacillus Leuconostoc*, *Carnobacterium*, and *Enterococcus* were the predominant species. Victoria-Leon et al., (2008) isolated eight strains of LAB from commercial sausages. The strains were heated in water baths to 50, 60 and 70°C, during 30-60 min. Four strains survived the treatments and were identified as *Lb. alimentarius*, *Lactococcus (L.) lactis*, *Lb. piscicola* and *Enterococcus sp.* These strains were considered thermotolerant. Ramírez-Chavarrín et al., (2010) isolated a total of 68 presumptive LAB from commercial cooked sausages collected in Mexico City supermarkets. Based on biochemical tests, 22 strains were selected and their thermotolerant capacity determined. Only 10 strains were considered thermotolerant after surviving thermal treatments at 70°C during 30 min. The genera identified by phenotypic and genotyping analyses were *Pediococcus*, *Lactobacillus*, *Aerococcus* and *Enterococcus*.

Chávez-Martínez et al., (2016) quantified and identified LAB in thirty samples of sliced cooked ham, reporting that enterococci showed the lowest count and lactobacilli the highest counts; 23.8% of the strains were identified as thermophilic *Lactobacillus*. Saucedo-Briviesca et al., (2017) studied the effect of probiotic thermotolerant LAB on the physicochemical, microbiological and sensorial characteristics in a meat batter. Two thermotolerant probiotic LAB were used: *Pediococcus pentosaceus (Ped.)* and *Enterococcus (Ec.) faecium*, which were inoculated to 5% in a meat batter. The results showed that the stability to cooking, expressible moisture, hardness and cohesion increased during storage in the batters inoculated with the 2 strains of LAB. The count of LAB increased in the inoculated meat batters and the coliforms decreased overall. When the strain mixture was used, inhibition of coliforms was total at day 6. Sensory analysis showed that judges detected when *Ec. faecium* was inoculated. Thermotolerant LAB can be used as functional ingredients in meat batters.

When a LAB demonstrates its resistance to thermal stress it is very possible that this bacterium can resist another type of stress. Fragoso et al., (2016) studied this and demonstrated that the use of thermotolerant probiotic LAB in fat reduced ice cream with inulin as fat replacer could be a good alternative to formulate symbiotic foods.

PROBIOTICS: DEFINITION AND CHARACTERISTICS

Several specific LAB strains are marketed on the basis of their beneficial effects on the consumer's health, representing an explosively growing market for the products containing these so-called probiotics (Bron & Kleerebezem, 2011).

Etymologically, the term probiotic is derived from the Greek language meaning "for life." The first definition of probiotics was coined by Lilly and Stillwell (1965) to describe substances produced by one microorganism that stimulate the growth of another, thus meaning the opposite of antibiotics. Later, Fuller (1989) redefined the term probiotics:

"Probiotics are live microbial feed supplements which beneficially affect the host animal by improving its intestinal microbial balance."

The FAO/WHO (2002) describes them as:

“Live microorganisms which when administered in adequate amounts confer a health benefit on the host.”

This is the more widely accepted definition.

The principal characteristics of probiotics include: tolerance to human gastric juice and bile, adherence to epithelial surfaces, persistence in the human gut, immune stimulation, antagonistic activity toward intestinal pathogens, production of antimicrobial substances, safety in food and clinical use, susceptibility to antibiotics and bile salt hydrolase activity (Parvez et al., 2006). Among the benefits of probiotics are improvements of intestinal health, enhancement of the immune response, reduction of serum cholesterol and cancer prevention (Kechagia et al., 2013).

The most common microorganisms used as probiotics are from the *Lactobacillus* and *Bifidobacterium* genera; other bacterial genera, including *Enterococcus*, *Streptococcus*, and *Escherichia*, are also used. Some strains of the fungus *Saccharomyces boulardii* are also considered probiotics (Mack, 2005).

THERMOTOLERANT LACTIC ACID BACTERIA AS PROBIOTICS

Ramírez-Chavarrín et al., (2013) evaluated 10 thermotolerant LAB (*Ped. pentosaceus* (4 strains), *Lb. plantarum* (3 strains), *Ec. faecium* (2 strains) and *Aerococcus viridans* (1 strain) to identify their probiotic properties. The results showed that 50% of the strains were intolerant to low pH and simulated gastric juice. All strains grew in taurocholic acid and bile concentrations greater than 0.3%, indicating they are good probiotic candidates. Less than 20% of the strains coaggregated with an *E. coli* indicator while 30% coaggregated with a *Salmonella* ssp. Eight of the strains exhibited good autoaggregation capacity at 24 h and all ten had a high adherence capacity for HEp-2 cells. The studied thermotolerant LAB are promising ingredients in the production of cooked meat products with probiotic potential. Alginate and other gelling hydrocolloids encapsulation of thermotolerant and probiotic LAB is a good alternative to protect them in their passage through the pH of the stomach (Totosaus et al., 2013).

Tatsinkou et al., (2017) studied the protective effect of minerals such as calcium and magnesium on probiotic strains. This protective effect is due to the fact that calcium and magnesium ions have the property of stabilizing certain structural proteins and even enzymatic ones. Their presence may prevent the rapid denaturation of membrane proteins. These results showed that mineral salts increase the thermotolerance and resistance to bile salts of probiotic strains. They concluded that calcium and magnesium could be used to monitor the viability of probiotic strains in probiotic products.

Hernández-Alcántara et al., (2018) isolated and evaluated the probiotic properties of six thermotolerant LAB. The bacteria were typed by determination of the DNA sequence of their 16S rRNA coding genes, as one *Ec. faecium* (UAM1 strain) and five *Ped. pentosaceus* (UAM2-UAM6 strains). *In vitro*, these strains showed desirable probiotic properties. These trials are promising for the application of *Ec. faecium* UAM1 as a novel probiotic strain in the food industry, since it can be employed as bioprotective culture due to its thermotolerant capacity in functional foods.

SYNBIOTICS

Synbiotics are used for the improved survival of beneficial microorganisms added to food or feed, and to stimulate the proliferation of specific native bacterial strains present in the gastrointestinal tract (Markowiak & Slizewska, 2017). Gómez-Chávez et al., (2011) studied the prebiotic effect of cacao flour on the growth of probiotic thermotolerant lactic acid bacteria in a meat batter. The *in vitro* growth of lactic acid bacteria using cacao flour as carbon source was acceptable compared with the growth obtained using glucose. No differences in physicochemical analysis were shown. Those authors concluded that the use of this kind of bacteria in cooked meat products leads to a foodstuff with high nutritional and symbiotic value that enhances microbial intestinal flora as a result of its intake.

Díaz-Vela et al., (2015) studied the effect of fruit peels as prebiotic and probiotic thermotolerant lactic acid bacteria in the structural characteristics of cooked meat products. Scanning electron microscopy showed the development of LAB in the sausages. In the control treatment (not inoculated with bacteria, no fruit peel flour added), some LAB colonies were visible between the components of the meat batter, above all after 20 days of storage. Analysis showed the production of exopolysaccharides by thermotolerant LAB. The incorporation of fruit peel flour into the formulation increased the number of bacteria in cooked meat emulsions.

Lactic acid bacteria viability was improved by the incorporation of different compounds during alginate ionotropic gel matrix coencapsulation, enhancing the resistance to acidic conditions as well. The strong prebiotic effect of inulin and apple marc flour was to enhance bacterial viability due to insoluble carbohydrate content, resulting in higher particle size with a higher number of viable bacteria. Symbiotic co-gelification of alginate gel matrix with prebiotic compounds to protect probiotics can be employed in order to ensure the delivery of probiotic strains in the colon throughout the gastrointestinal tract (Serrano-Casas et al., 2017).

CONCLUSION

Lactic acid bacteria have been used for many years in fermented meat products. It has been shown that LAB can produce heat shock proteins (Hsp) that make them capable of resisting the heat treatments suffered by meat products in their preparation. Additionally, these bacteria may have probiotic characteristics. The use of probiotic thermotolerant lactic acid bacteria in cooked meat products is a good alternative in the manufacture of functional meat foods.

ABSTRACT

The lactic acid bacteria (LAB) that belongs to the *Lactobacillaceae* family is classified into fifteen different genera. Some LAB, including the *Lactobacillus casei*, *Lb. delbrueckii*, *Lb. acidophilus*, *Lb. fermentum*, *Lb. reuteri*, *Lb. sakei*, and *Lb. plantarum*, are recognized worldwide as probiotics. International agencies such as the United Nations' Food and Agricultural Organization and the World Health Organization have defined probiotics as "living microorganisms of which when administered in adequate amounts confer a health benefit on the host." LAB selection as probiotics must include criteria such as safety for human consumption, stability against acid and bile conditions, and the capacity to colonize the human gastrointestinal tract. Probiotic microorganisms have been associated with improvements in the host's health, which has stimulated the consumption of LAB-added functional foods. There are some concerns associated with probiotics survival during manufacturing, storage, and specific preparation processes for the final product. Different approaches have been studied in order to increase LAB feasibility in meat products. Microencapsulation could be employed as an alternative since it is a LAB protective method consisting of isolating the microorganism to obtain spherical-shaped and micrometer-sized products, in which a membrane shields the LAB. The probiotics ought to survive and dominate other microorganisms present in the food product, evidencing the use of microencapsulation for cellular viability increase. The probiotics used in fermented meat products are primarily associated with salami, which differs in terms of raw material composition, ripening time, appearance, and flavor. Fermented meat products encounter some barriers such as pH, water activity, lower sugars content, temperature, and preparation form limitations. On the other hand, the

* Corresponding Author's Email: daneyssa@hotmail.com.

instinctive search for better a quality of life demands practical and functional foods and the added value is imperative to make a difference in the meat food industry. In this context, microorganisms are added to food aiming at increasing its properties, creating new functional foods capable to promote healthy benefits to the host. This chapter focused on the microencapsulated probiotic LAB potentials and their application in fermented meat products.

INTRODUCTION

The concern about food and health is reflected in the lifestyle of the population. Food habits change according to what is offered and made available in the market, favoring and encouraging the consumption of foods with functional properties. Consumers' acceptance of functional foods is complex and influenced by product-related factors such as sensorial characteristics, price, healthy ingredients, related claims, and also by consumer-related factors (Shan et al., 2017).

Functional foods potentially promote health benefits, they can provide nutrients associated with probiotics that may contribute diminishing intestinal disorders (Kapasob, Kerdchoechuen & Laohakunjit, 2018). Probiotics are defined as microorganisms that, under certain conditions, confer the host some health benefits. Many LAB are probiotic microorganisms and they are especially associated with milk-based products. The most important LAB probiotic genera are *Lactobacillus* and *Bifidobacterium* (Ferreira & Silva, 2016).

Probiotics are associated with intestinal microbiota control, pathogens population decrease, intestinal microbiota stabilization after the use of antibiotics, lactose digestion, constipation relief, host immune system stimulation, short chain fatty acids production (acetate and butyrate), inhibitory effects on mutagenicity, and colon cancer risk reduction (Ferreira & Silva, 2016).

Probiotics offer some limitations for their application in foods. There are some concerns associated with probiotics survival during manufacturing, storage, and specific preparation processes to obtain the final product. In this respect, microencapsulation ought to improve the probiotic stability, proving to be an interesting alternative for adverse conditions. Different microencapsulation methods and wall materials have been tested in order to ensure high stability.

Pork consumption has been on the rise and is expected to reach 43,619 tons worldwide by 2026 (Oecd/Fao, 2017). A great part of its consumption is related to industrialized products, and it should be diversified to achieve consumer's preference. Probiotic meat products are mainly associated with fermented meat products. Salami is an excellent alternative for probiotic addition because it could be consumed without preheating.

In this way, LAB microencapsulation appears as an alternative to producing probiotic meat products, by breaking technological barriers. Additionally, probiotics could improve food safety and preservation, sensory characteristics development, acceptability, nutritional value, and health benefits.

LACTIC ACID BACTERIA

LAB are Gram-positive ubiquitous microorganisms, which are found in plants, mammals' intestinal mucosa, as well as in fermented foods (Teneva-Angelova et al., 2018). LABs have a long history of use for food production and conservation, as they are comprised of a wide group of microorganisms. Originally, LAB group included four kinds of great importance genera for food industry, including *Lactobacillus*, *Leuconostoc*, *Pediococcus*, and *Streptococcus*. Currently, it consists of fifteen classified genera based on morphology, glucose fermentation mode, the configuration of lactic acid produced, growth at certain temperatures, high NaCl concentration and pH, and catalase activity (Table 1) (Kalschne et al., 2015).

LAB are mesophilic, non-sporogenic, devoid of cytochromes, facultative anaerobes, fastidious, acid tolerant, catalase, and oxidase negative (Khalid, 2011). However, their main characteristic is carbohydrates fermentation with lactic acid production. The differences between homofermentative and heterofermentative carbohydrate metabolism involves LAB genetics and their physiological basis. Homofermentative carbohydrate metabolism use aldolase and hexose isomerase enzymes by the Embden-Meyerhof-Parnas pathway to produce two lactic acid molecules from a one glucose one. In contrast, the heterofermentative metabolism uses phosphoketolase enzyme by hexose monophosphate pathway or pentose degradation of glucose to produce lactic acid, ethanol, and carbon dioxide from glucose (Kalschne et al., 2015).

The *Bifidobacterium* genus is classified as a LAB since it shares a few characteristics, despite being phylogenetically unrelated. *Bifidobacterium* differs from other LAB genera on glucose fermentation mode, which occurs via fructose-6-phosphate due to the presence of fructose-6-phosphate phosphoketolase enzyme (Mazo et al., 2009).

Table 1. LAB key phenotypic characteristics

Genera	Morphology	CO ₂ from glucose	Lactic acid isomer	Growth at 10°C	Growth at 45°C	Growth in 18% NaCl	Growth at pH 4.4	Growth at pH 4.5	Catalase activity
<i>Aerococcus</i>	C ^a	-	L	+	-	-	-	-	-
<i>Atopobium</i>	C/R	-	-	-	-	-	-	-	-
<i>Bifidobacterium</i>	R	+ ^b	L	-	+	-	-	-	-
<i>Brochothrix</i>	C/R ^d	-	L	-	- ^f	-	-	-	+
<i>Carnobacterium</i>	R	- ^e	L	+	-	-	-	-	-
<i>Enterococcus</i>	C	-	L	+	+	-	+	-	-
<i>Lactobacillus</i>	R	±	D, L, DL	±	±	-	±	+	- ^f
<i>Lactococcus</i>	C	-	L	+	-	-	±	-	-
<i>Leuconostoc</i>	C	+	D	+	±	-	±	-	-

Source: Adapted from Kalschne et al., (2015).

C: cocci; R: rod-shape; L, D and LD: optical isomers; +: positive; -: negative; a: cocci may also be tetrad formation; b: differ from bacterial homo and heterofermentative on fermentation of glucose, which occurred via fructose-6-phosphate; c: grow did not occur at pH 5.0 or lower; d: in older cultures the rod may give rise to coccoid forms, which will develop into rod forms when subcultured onto a suitable medium; e: small amounts of CO₂ from glucose might be produced; f: growth did not occur at 37 °C; f: can be present pseudocatalase activity.

LAB are usually of great biotechnological interest due to their morphological, metabolic, and physiological characteristics. The addition of LAB to foods have some positive characteristics such as a probiotic appeal, desired sensory characteristics development in fermented meat products, and food safety due to bacteriocin production and/or also due to competition with the microbiota present in food (Domínguez, Agregán & Lorenzo, 2016; Juturu & Wu, 2018; Ahn, Kim & Kim, 2017; Ruggirello et al., 2018).

Probiotics

Probiotics have been getting various definitions since their discovery. According to Fuller (1989) probiotics are living microbial food supplements that beneficially affect the host by improving their intestinal microbiota balance. International agencies such as the United Nations' Food and Agricultural Organization and the World Health Organization defined probiotics as "living microorganisms that when administered in adequate amounts confer a health benefit on the host" (Hill et al., 2014; FAO/WHO, 2001). In this way, a food is considered functional in terms of probiotic activity when it generates a beneficial effect to the host that receives it, besides its nourishing ability.

Probiotics are microorganisms present in the intestine on a constant survival contest and they are associated with many beneficial effects at this level, as was explained above (Ferreira & Silva 2016). Additionally, a recent study about *Lactobacillus plantarum* KX881772, a new probiotic from camel milk, observed potential anti-diabetic activities in camel fermented sausages and beef by α -amylase (A) and α -glucosidase (B) inhibitions, and they also showed anti-hypertensive and cytotoxicity activities (Ayyash et al., 2019).

LAB selection as probiotics includes anti-pathogenic activity and other criteria for safety assessment such as taxonomy identification, virulence absence, enterotoxins production, hemolytic activity, and transferable antibiotic resistance genes. Additionally, probiotics must exhibit stress tolerance to salivary and gastric enzymes, body temperature, low pH, gastric juice and bile salts, and adhesion ability to colonize the human gastrointestinal tract demonstrating functional efficacy (Distrutti et al., 2016; Pereira et al., 2018).

Strains of probiotics for use in humans have been selected mainly among the genera *Lactobacillus* and *Bifidobacterium*. They are commonly found in the intestines and mucosal surfaces of healthy humans or in spontaneously fermented foods (Balakrishnan & Floch, 2012; Vinderola et al., 2017). However, Pereira et al., (2018) also emphasized that *Lactococcus*, *Streptococcus*, and *Enterococcus* have a long history of safe use as probiotics.

Lactobacillus is the main LAB genus present in the small intestine, and it is susceptible to changes due to the entry of exogenous bacteria; thus *Lactobacillus* consumption during several days might be necessary to achieve the probiotic effect. In contrast, *Bifidobacterium* is mainly present in the large intestine and it does not offer a practical use as probiotics due to difficulties of its isolating and manipulating (anaerobiosis) and also, it does not tolerate acidic environments, hampering its use when fermented products are used as carriers. The microbiota in the large intestine is more stable and suffers less influence from exogenous bacteria due to the effect of consumed prebiotics. However, the large intestine is the first one to be attacked by antibiotics (Ferreira & Silva, 2016).

In this sense, there are some concerns associated with probiotics survival during manufacturing, storage, and specific preparation processes for the final product. In general, the use of LAB in food products depends on the lactic acid amount reduced, the type of glucose fermentation (homo or heterofermentatives), growth at different temperatures, and the tolerability to acidic and alkaline substances.

The standard for health-claiming-probiotics-added foods follows FAO/WHO recommendations per plate count with a minimum 10^6 to 10^7 UFC/g (FAO/WHO, 2001). Similarly, Minelli et al., (2008) recommended 10^6 CFU/mL and 10^8 CFU/mL as minimum probiotic concentrations in the small intestine and in the colon, respectively.

There are some concerns associated with the survival of probiotic strains during the manufacturing, storage, and high quantification number in the final product (Leroy, Verluuyten & De Vuyst, 2006). Different approaches have been studied in order to increase the resistance of these sensitive microorganisms to adverse conditions, being probiotics microencapsulation one of them. Many authors have reported the advantages of this method in prolonged preservation and controlled release of probiotics (Etchepare et al., 2015; Shori, 2017; Huq et al., 2017; Prisco & Mauriello, 2016; Arepally & Goswami, 2019; Mao et al., 2018).

MICROENCAPSULATION

Different approaches have been studied in order to increase LAB feasibility in meat products. Microencapsulation is a promising alternative that could be employed as a LAB protective method, consisting of the coating of microorganisms to obtain spherical-shaped and micrometer-sized products, in which a membrane shields the LAB (Arepally & Goswami, 2019). The probiotics can survive and dominate over other microorganisms present in the food product, emphasizing the use of microencapsulation to increase cellular viability.

Microencapsulation is a coating process of small particles or droplets; or the compounds incorporation in a homogeneous or heterogeneous matrix, obtaining small capsules. Microencapsulation promotes a physical barrier between the core and wall materials, enabling a controlled release (Prisco & Mauriello, 2016).

Probiotics can be kept viable by microencapsulation, depending on processing conditions both during food manufacturing process and in the final product. Microencapsulation allows the coating material, capable of withstanding extrinsic conditions adverse to microorganisms, to protect the culture. On the other hand, coating should be released upon reaching the intestines so that probiotics can be able to perform their functions there (Arslan et al., 2015; Martín et al., 2015).

Several factors affect the protection and survival of encapsulated probiotics during gastric transit. The most important factors are probiotic strains' acid resistance properties, wall materials and their concentrations, encapsulation methods, and polymers incorporation in the matrix (Shori, 2017).

Microencapsulation has different uses, namely the food industry has reported the implementation of increasingly complex formulations with microorganisms encapsulated in fermented meat; the addition of polyunsaturated fatty acids susceptible to auto-oxidation in milk, yogurts or ice creams; and the use of highly volatile flavor compounds in instant foods,

which oftentimes can only be achieved by microencapsulation (Khan et al., 2011; Gharsallaoui et al., 2012).

Microencapsulation Techniques

The most common methods used for probiotic microencapsulation are emulsion, spray drying, and extrusion, due mainly to their efficiency and low costs (Santos et al., 2019; Holkem et al., 2017; Ramos et al., 2018; Shori, 2017; Prisco & Mauriello, 2016). Furthermore, complex coacervation is an emerging method also used for probiotic encapsulation that results in an increase of probiotics feasibility and great encapsulation efficiency (Bosnea, Moschakis & Biliaderis, 2014; Bosnea, Moschakis & Biliaderis, 2017). Gelation, including the alginate-based, has been investigated (Kia, Alizadeh & Esmaili, 2018; Huq et al., 2017). Often, probiotic microcapsules obtained by coacervation, emulsion or gelation methods are posteriorly freeze-dried to ensure preservation and microorganisms' viability (Silva et al., 2018; Halim et al., 2017; Huq et al., 2017).

Choosing microencapsulation for a specific process will depend on factors such as particle size, the microcapsules biocompatibility and biodegradability, core and coating physical and chemical properties, microcapsules application, proposed active core release mechanism, and process costs (Dubey, Shami & Bhasker Rao, 2009). For probiotic applications, it is important that microcapsules be water-insoluble so the structure could be maintained during food and beverages processing, and through the digestive system (Ramos et al., 2018).

The spray drying technique is viable and effectively applicable for microorganism's encapsulation. This microencapsulation technique has been largely used for microorganisms' preservation (Arslan-Tontul & Erbas, 2017; Arepally & Goswami, 2019; Santos et al., 2019; Loyeau et al., 2018; Mao et al., 2018; Prisco & Mauriello, 2016). It may offer advantages such as ease of operation and cost-effectiveness, and that it is already available for industrial use. The atomization process consists in numerous droplets formation by solution, emulsion or suspension spraying into the drying chamber where they make contact with the hot gas (air or nitrogen) for subsequent dehydration, transforming the liquid component in a powdered solid one, later recovered in the cyclone (Burgain et al., 2011).

The risk of cell death associated with high temperatures is one of the disadvantages of spray drying. However, some authors mention temperatures ranging from 70 to 130 °C in the drying chamber to promote microorganisms' microencapsulation (Anekella & Orsat, 2013), considering that the contact time between microorganisms and the heat source is quite short, and the chamber outlet temperature is around 30-40 °C lower than the inlet temperature (Mao et al., 2018).

Wall Materials

The correct selection of wall material is associated with microcapsules' stability, process efficiency, and active core protection level. The ideal wall material should be non-reactive with the core, capable to seal and keep it within the capsule, provide core maximum

protection against adverse conditions, no unpleasant taste, and be economically feasible (Nazzaro et al., 2012).

For food applicable microencapsulation, the wall materials normally include proteins (whey protein, soy protein, caseinate, and gelatin), carbohydrates (starch, alginate, maltodextrin, pectin, inulin, gum arabic, chitosan, carrageenan, cellulose nanocrystal, β -cyclodextrin, dextrans, and fructo-oligosaccharides) or their mixtures (Etchepare et al., 2015; Shori, 2017; Huq et al., 2017; Prisco & Mauriello, 2016; Arepally & Goswami, 2019; Mao et al., 2018; Loyeau et al., 2018; Arslan-Tontul & Erbas, 2017). Most wall materials do not have all the desired properties, thus the mixture of two or more is a common practice.

The release of microcapsules content at controlled rates could be triggered by shearing, heating, pH, and enzymatic action (Lam & Gambari, 2014) and are mainly related to the wall material employed. Carbohydrates are often mixed with proteins in order to improve emulsifying and film-forming properties during their encapsulation (Mao et al., 2018; Loyeau et al., 2018).

In addition to being biodegradable and biocompatible materials, the wall materials should release the microencapsulated probiotics in the intestines without earlier release due to the wall materials solubility in water. Thus, probiotic microcapsules pH dependence is an interesting alternative to release the microorganisms at the correct time in the small intestine. Most foods have acidic pH, and the conditions for probiotics in the digestive tract before reaching the small intestine are acidic; however, pH increases when the probiotics enter in the intestine, surpassing neutrality and reaching alkaline levels. In this way, pH-dependent wall materials, especially with probiotic release at alkaline pH are the most favorable ones.

PROBIOTIC LAB ADDED IN FERMENTED MEAT PRODUCTS

Several foods of various products categories have been added with probiotics such as bakery products (bread, biscuits, chocolate soufflé, and stuffed cakes), fruit and vegetable juices (acerola nectar, longan, cranberry, pomegranate, berries, carrot, orange, peach, and apple), dairy products (yoghurt, ice cream, and fermented soured milk beverage), cheese (feta, cheddar, white Iranian brined cheese, white brined cheese, kasar, mozzarella, fiordilatte, pecorino, and oxaca) and others (i.e., mayonnaise). For meat products, only fermented ones have been associated with probiotics (Prisco & Mauriello, 2016).

Fermented meat products such as salami have some technical limitations regarding probiotics addition. Barriers such as pH, water activity, lower sugars content, and preparation form limitations, mainly associated with high cooking, baking, and frying temperatures need to be surpassed. In order to overcome this problem, the addition of microencapsulated probiotics in fermented meat products has been discussed (Barbosa et al., 2015; Muthukumarasamy & Holley, 2006; Macedo et al., 2008). However, these food products added with microencapsulated probiotics should be consumed without pre heating at preparation in order to preserve the microorganisms.

Salami is prepared by mixing all of its ingredients (pork shoulders, pork fat, salt, curing salts, sugars, spices, antioxidant, and starter culture), stuffing in artificial casings, fermentation/drying for a few days, and ripening for some days up to reaching the desired water activity in the final product (Alamprese, Fongaro & Casiraghi, 2016).

The fermentation process is defined as the anaerobic metabolism of carbohydrates by microorganisms. It has been used to extend foods expiration date, with an important role in diets worldwide offering a variety of benefits. Starter cultures were initially used for food preservation, including sensory characteristics, acceptability, nutritional value, and food safety improvements while also providing diet diversification (Malo & Urquhart, 2016).

Salami starter cultures generally combine the *Micrococcaceae* family represented by *Staphylococcus* (S.) *xylosus* and *S. carnosus* species, and LAB *Pediococcus* (Ped.) *pentosaceus*, *Ped. acidilactici*, and *Lactobacillus* (Lb.) *sakei*. The *Debaryomyces hansenii* yeast and *Penicillium nalgiovense* mold were also included in some commercial starter cultures (Alves et al., 2018).

The cited *Staphylococcus* species are associated with bacteriocins production and lipolytic and proteolytic activities, while the LAB are associated with the lactic acid production. *Debaromyces hasenni* and *Penicillium nalgiovense* also have lipolytic and proteolytic activities. *Penicillium nalgiovense* provide a fungal mycelium on salami's external surface, offering a protective effect against some undesirable microorganisms during the ripening process, and it is a good quality indicator by manufacturers (Galvalisi et al., 2012; Mattei, 2012).

In terms of starter cultures and probiotics, two important issues need to be mentioned. First, not all LAB used in food products fermentation are considered probiotic, since the probiotic is related to the colonization of the intestines benefiting its host. Second, the fermentative LAB microorganisms are not always present in amounts required to obtain the beneficial properties of a functional food. Therefore, there is a close link between the possibilities that a fermenter LAB be a microorganism with probiotic characteristics.

Overall, during the fermentation and ripening processes, the sugar present in the salami is fermented by homofermentative *Lactobacillus* and converted to organic acids, mainly lactic acid by Embden-Meyerhof-Parnas, resulting in pH reduction (Krummenauer et al., 2015). The pH decreases and reaches the isoelectric point of proteins (neutral charge) promoting myofibrillar proteins insolubilization and the consequent water loss by dehydration.

Therefore, acid pH is one of the main physicochemical and sensorial characteristics of salami, which usually reach values around 5.0 and, increasing to 5.3 after proteolysis (Massaguer, 2006). Acid pH also works as a barrier to the development of undesirable microorganisms in the product, especially when associated with low water activity.

Probiotic microorganisms in salami must withstand the product's (pH from 4.5 to 6.0) and the human stomach's (pH from 1.0 to 3.5) acidic conditions. Microencapsulation allows greater probiotic stability against adverse pH conditions. Alternatively, the wall material could be pH dependent as it remains intact at acidic pHs but is disrupted by releasing the probiotics at the small intestine alkaline pH (pH around 7.4 in the jejunum and up to 7.7 in the ileum) (Ekmekcioglu, 2002). In this sense, more studies should be conducted to evaluate the probiotic effect of microencapsulated LAB applied in a fermented meat product.

CONCLUSION

The consumers' search for better quality of life and the increase in quality of life demand practical and functional foods and the added value is imperative to make a difference in the

meat industry. Functional foods are an option in order to add value and make a difference in the meat industry for the consumers that search for better quality of life. Probiotic LAB are recognized to offer different possibilities in physicochemical and sensory innovations and microbiological safety. In this context, alternatives such as probiotic microencapsulation help to protect the microorganisms and promote a wide range of options to enrich complex food matrices with probiotics. Among the different microencapsulation techniques, spray drying is characterized as ease of operation and cost-effective for microorganism's microencapsulation. Different wall materials are available, and the combination of carbohydrates and proteins normally promote greater functional properties. Considering that the meat products industry has been growing year by year in line with an increasing demand for functional foods, efforts have been made to produce functional meat products. Fermented products such as salami are an excellent alternative for probiotics addition, as they are consumed without any preheating, a thermal process that could kill microorganisms.

Chapter 295

LACTIC ACID BACTERIA RESPONSES TO OSMOTIC CHALLENGES

***Maria K. Syrokou, Spiros Paramithiotis*
and Eleftherios H. Drosinos***

Laboratory of Food Quality Control and Hygiene,
Department of Food Science and Human Nutrition,
Agricultural University of Athens, Athens, Greece

ABSTRACT

Lactic acid bacteria (LAB) stress responses and adaptation mechanisms have been the epicenter of intensive study over the last decades due to their importance for food industry. Among the stresses encountered, cells are subjected to osmotic pressure during production of starter cultures as well as during food fermentations. Cells react to fluctuations in external osmotic pressure by accumulating or releasing compatible solutes, which aid the microorganism to support a constant positive turgor, by balancing the osmotic difference between cell surroundings and cytosol. The function of cells is determined by the semipermeable attributes of cell membrane, functioning as a barrier for most solutes. The use of specific osmoprotectants is facilitated by certain transporters, whose intercommunication with membrane lipids defines their response to osmotic up- and down- shifts. Glycine betaine (GB) is considered the most efficient osmoprotectant in restricting the repressive effects of NaCl, while carnitine (CA) offers protective action to LAB in a more moderate way. In case the osmotic pressure drops, compatible solutes are released via mechanosensitive channels (MSC), acting as emergency release valves. In the present chapter current knowledge on the LAB osmoprotection mechanisms along with aspects of their genomic and transcriptomic organization is assembled and critically reviewed.

INTRODUCTION

Lactic acid fermentation has been used for centuries as a method to preserve foodstuff. It has been exercised on practically any type of substrate, either of plant or animal origin. Through this biotransformation, the final product gains enhanced shelf-life, sensorial properties and nutritional value. Lactic acid bacteria that drive this process have been in the epicenter of intensive study over the last decades. Their responses to environmental stimuli as well as their metabolic properties are constantly assessed and our understanding of their physiology accordingly improved.

During fermentation, lactic acid bacteria have to address a series of stresses, such as the osmotic stress due to NaCl that is used as a selective agent, acidic stress due to the acidity that develops as a consequence of their metabolic activity, oxidative stress due to the production of reactive oxygen species (ROS), starvation stress due to the depletion of the available nutrients, etc. It can be claimed that growing in stressful environments is the routine for LAB. In order to address effectively these challenges, a series of tuning activities, collectively referred to as stress response, is required.

Osmotic stress is among the most important ones from a technological perspective. It is the result of dissolved solute abundance and quite different from the desiccation stress, which is the result of lack of water. It may be encountered during production of starter cultures; their preservation may include dehydration and/or freezing. In addition, as already mentioned, the presence of NaCl creates an osmotic pressure to the cells. Finally, the increased osmolarity that characterizes the upper small intestine needs to be effectively addressed in order to exert all the health benefits through the probiotic action.

The aim of the present chapter is to collect all available information regarding the osmoprotection mechanisms of LAB as well as aspects of their genomic and transcriptomic organization and present them in a comprehensive way.

BACTERIAL RESPONSES TO OSMOTIC STRESS

Bacteria protect themselves against detrimental fluctuations of external osmotic pressure by accumulating compatible solutes, i.e., water soluble compounds that may accumulate intracellularly without affecting negatively any cellular functions. In that way the osmotic difference between the environment and cytosol is counter-balanced, and water loss and plasmolysis are prevented. These osmolytes may be either *de novo* synthesized or transported from the environment through specific permeases; depending on the biosynthetic capacity of the bacterium and the growth medium. The latter constitutes the most rapid and effective response, since the former may require additional time and is therefore slower, especially if protein synthesis is involved. Compatible solutes can be classified into three categories: a) sugars and polyols, such as trehalose and glycerol; b) amino acids, such as glutamate and proline; c) amino acid derivatives, such as betaines, ectoines and N- acetylated amino acids. Adjustment of their intracellular concentration is achieved through the coordinated action of specific transporters and mechanosensitive channels (Figure 1). Apart from their osmoprotective action, additional roles have been claimed for glycine betaine, ectoine and proline. The first has been reported to assist *in vivo* protein folding (Bourot et al., 2000) as

well as protection against cold and heat stress (Holtmann & Bremer, 2004; Hoffman & Bremer, 2011); ectoine against cold and heat stress (Bursy et al., 2008; Kuhlmann et al., 2011) and proline is involved in protein stability, ROS scavenging, redox homeostasis and signaling (Liang et al., 2013).

Cell wall of Gram positive bacteria is comprised of a peptidoglycan layer (PG), also known as murein, enclosing the cytoplasmic membrane. This polymer consists of N-acetylglucosamine (GlcNAc) and N-acetylmuramic acid (MurNAc), cross linked by peptide side chains (Chapot-Chartier & Kulakauskas, 2014). The penicillin binding proteins (PBPs) play a crucial role in PG synthesis, which are involved in glycosyltransferase and transpeptidase reactions. Except for the presence of PG sacculus, cell wall of Gram positive bacteria includes teichoic acid polymers as well, being separated into wall teichoic acid (WTA) and lipoteichoic acid (LTA). The former is covalently linked to the PG molecule, while the latter is attached to the membrane by a lipid ligand. The backbone chains of both WTA and LTA can be replaced by D- alanine residues, which reduce the negatively charged phosphate groups of TAs by offering protonated amino groups, thus regulating ionic attributes of TAs. Finally, the existence of O- acetyl groups in PG molecule is highly related to resistance to lysis by hydrolases. LAB lysis/autolysis is a defining parameter for controlling and accelerating ripening events and contributes to the sensory profile of the end product.

In hypertonic conditions, where the concentration of solutes in the environment is higher than that of the cytosol, osmotic pressure stimulates water efflux, resulting in loss of turgor or plasmolysis. Conversely, in hypotonic circumstances, where the culture media is characterized by lower concentration of solutes, compared to cytosol, water diffuses into the cell, increasing its volume, thus leading to cell lysis. The cell membrane plays a crucial role in osmotic regulation; it acts as selective barrier, hindering the passage of solutes, while allowing water permeation in both directions. An alternative response to osmotic gradient includes water transportation through channel like structures, called aquaporins of the MIP (major intrinsic protein) family. A subset of aquaporins, aquaglyceroporins are responsible for glycerol transit. There is evidence that except for water and glycerol, some aquaporins transport CO₂, NH₃, NO, NO₂, H₂O₂ and even ions, K⁺, Cl⁻ (Verkman, 2014).

COMPATIBLE SOLUTES ACCUMULATION IN LAB

The main response of LAB to osmotic challenges, involves the transport of compatible solutes from the surrounding media, since they are characterized by rather narrow biosynthetic potentials. The selection of specific osmoprotectants is facilitated by certain transporters, whose intercommunication with membrane lipids defines their response to osmotic up- and down- shocks.

The beneficial effect of a number of potential osmoprotectant solutes has been experimentally evaluated for a rather restricted number of LAB species, namely *Enterococcus* (*Ec*). *faecalis*, *Lactobacillus* (*Lb*). *plantarum*, *Lactococcus* (*Lc*). *lactis*, *Oenococcus* (*O*). *oeni*, *Pediococcus* (*Ped*). *pentosaceus* and *Tetragenococcus* (*T*). *halophila*, and the results are summarized in Table 1. In all cases, except for *O. oeni*, glycine betaine and carnitine have been reported to effectively restore growth under osmotic pressure. Further examination revealed that the *O. oeni* genome lacked genes homologous to the ones encoding the

transporters of glycine betaine and proline that have been reported for *Lb. plantarum* and *Lc. lactis* (Le Marrec et al., 2007). Except from the accumulation of quaternary ammonium compounds, adjustment of specific amino acids concentration inside the cytosol represents a different strategy to alleviate the adverse effects of osmotic challenges. Robert et al. (2000) reported the accumulation of glutamate, proline and aspartate in *T. halophila* under osmotic constraint. However, uptake of the specific amino acids was restricted in the presence of glycine betaine in a high- osmolarity medium. Similar effect, where concentrations of alanine, glutamate and proline increased in the absence of glycine betaine, was also observed in *Lb. plantarum* (Glaasker et al., 1998). In contrast to the previously mentioned studies, glycine betaine had no protective effects on *O. oeni*, while exogenously supplemented aspartate was able to alleviate the restrictive action of osmotic up- shifts on the cell turgor (Le Marrec et al., 2007). Finally, ectoine, a compatible solute found in halophilic microorganisms, exerted protective effects on *T. halophila* stressed cells (Baliarda et al., 2003b). One last approach reported, includes exogenously supplied osmolytes, such as proline and glutamate-containing peptides conferring protective effects on *O. oeni* sugar induced stressed cells (Le Marrec et al., 2007). Its role as osmoprotectant has been also reported for protease, PrtP, being activated during growth of *Lb. casei* in hyperosmotic conditions (Piuri et al., 2005).

LAB CYTOPLASMIC MEMBRANE AND OSMOTIC STRESS

As previously mentioned the cell cytoplasmic membrane functions as a barrier for most solutes, while is highly permeable to water molecules, thus its coordinated response to osmotic challenges regulates growth restoration. Degree of saturation, fatty acid (FA) composition and size of cells are attributes directly connected to membrane stability, and their behavior in hypertonic media determines the osmotic adaptation of cytoplasmic membrane. It has been shown that proline transport on the hyperosmotic medium of *T. halophila* led to an increase in the amounts of unsaturated FA, as well as the levels of cyclopropanoic FA (He et al., 2017), determining its crucial part in the regulation of fatty acid composition. However, it has also been reported that salt stress conditions favor the saturation degree of FA, often accompanied by FA cyclization, with the latter one being perceived as a process of controlling membrane fluidity (Machado et al., 2004). The presence of saturated FA was also validated by Tymoczyszyn et al. (2005), as a basic component of membrane rigid structure of *Lb. bulgaricus* grown in MRS, supplemented with polyethylene glycol (PEG). In addition a smaller shrinkage of cells, grown in MRS-PEG, was observed due to a higher anisotropy rate (a capability to exhibit variations in physical properties along different molecular axes). Similarly the existence of larger cells of *Lb. casei* in osmotically stressed conditions compared to those under unstressed, was also documented by Piuri et al. (2005).

Growth under high salt circumstances has been shown to facilitate the access of antibiotics to their target, validated by the increased sensitivity of cells to nisin (Piuri et al., 2005; Palomino et al., 2013). This observation was attributed to a decrease in peptidoglycan (PEPG) cross- linkage, caused either by a lower expression of PBP genes or by discrepancies in their appropriate folding in the cell envelope. Another alteration during growth of *Lb. casei* under hypertonic media was the decreased production of a cell wall component, namely lipoteichoic acid (LTA). The specific change was followed by a decline in LTA D-alanylation, generating a negatively charged cell wall, thus hindering the passage of Na⁺ to the cytoplasm. Decreased LTA substitution by D-alanine residues in combination with the participation of LTA in attachment of autolysins develops a PEPG more vulnerable to lysis. Lysis of LAB is crucial for the development of texture and flavor in food products and the harmony between autolysed and intact cells determines the fate of various ripening events.

Osmoprotectants are accumulated in the cytosol via active transport (Figure 1), upon osmotic up- shifts; however, upon decrease of the osmotic pressure, they are released from the cell via mechanosensitive channels (MSC). In fact, MSC function as biological emergency release valves, by facilitating a compatible solute efflux, having been accumulated in the cytosol, upon osmotic stimulation of the OpuA transport system (Booth & Blount, 2012). As the OpuA uptake system is activated by sensing the interactions between protein module and lipid membrane, so do MSC, which sense possible distortion of the lipid bilayer. The osmoprotectant role of MSC was determined with the presence of two MSC in *E. coli*, namely MscS (mechanosensitive channel small conductance) and MscL (mechanosensitive channel large conductance) (Levina et al., 1999). The MSC study has been restricted in LAB, from which only the *Lc. lactis* mechanosensitive solute transfer system has been reported (Folgering et al., 2005). Their results revealed the presence of two different genes, *yncB* and *mscL*, regulating MscS and MscL, respectively, with MscL being preferentially activated by *Lc. lactis* under osmotic down- shock. Despite the fact that *yncB* gene was transcribed, MscS

stimulation was not confirmed. MscS and MscL detected in *Lc. lactis* shared many similarities with those identified in *E. coli*; nevertheless the medium ionic strength had no effect on the transcription process of the corresponding genes in the case of *Lc. lactis*, but was determinant for the gene expression in *E. coli*.

Mechanosensitive ion channels play a crucial role in sensing membrane tension within a cell's surroundings and transducing mechanical constrain into an electrochemical response. The *E. coli* MscS homoheptameric structure (MscS-Ec) is strongly dependent on the TM1-TM2 region, which senses membrane distortions and its interaction with TM3 helix, forms specific channels, comprised of Gly and Ala residues (Booth & Blount, 2012). The block complex, identified in the open structure of A106V mutant of the MscS-Ec channel, is based on the presence of 2 rings of Leu residues and is highly hydrophobic, hindering the passage to ions and water. The transition of close to open state of MscS starts with the TM1-TM2 helix being triggered by ionic changes in lipid membrane. Then, a further stimulation of the TM3 domain follows, which is accompanied by a slight rotation, resulting in the discharge of Leu residues and generating the open configuration. As for MscL, they respond to osmotic challenges, sensed by alterations in membrane tension, by opening a large water- filled pore, thus aiding as osmoprotective emergency valves. MscL was first identified in *E. coli* constituting a non- selective ion pathway, but a three dimensional (3D) conformation of MscL from *Mycobacterium tuberculosis* (MtMscL) revealed the basic elements defining its structure. In brief, crystal structure of MtMscL indicates a highly α - helical homopentamer, with N- and C- terminal regions facing the cytoplasm, TM1, TM2 transmembrane helices and a periplasmic loop connecting them (Chang et al., 1998; Pivetti et al., 2003; Bavi et al., 2017).

Figure 1. Schematic representation of a generic LAB osmotic adaptation mechanism.

Upon hyperosmotic stress, osmolytes are accumulated in the cytoplasm, via a compatible solute uptake system (SUS), while they are released to the culture media via mechanosensitive channels (MSC), upon osmotic downshifts. Green color designates open configuration to the respective system; red color designates close configuration.

Questionable was the role of C- terminal domain in the regulation of the MscL opening, with many studies supporting its complete dissociation, and others arguing that the helical bundle remained intact, all along its transition pathway from close to open state. Bavi et al. (2017)

reported the partial dissociation of the MscL-Ec channel under different conditions, favoring the open channel conformation. More analytically, the results showed that the gating of the MscL channel was accompanied by a restricted dissociation of the top part of the C- terminal region, due to weak hydrogen bonds between subunits, while the residual domain of the central and the end bundle remained associated. A study employing various experimental circumstances for studying 3 different states of MscL, close, intermediate and open was performed by Perozo et al. (2002). The conversion pathway of close- intermediate conformation initiates imperceptible shifts in the transmembrane helix, TM1; while TM2 does not rotate about its central axis. Further transition to the open state, is followed by crucial structural changes, with TM1 actively participating in the channel gating. The transition to the open MscL conformation, escorted by the presence of an open pore, 30- 40 Å° in diameter, was triggered by adding lysophosphatidylcholine (LPC) into phosphatidylcholine (PC) vesicles.

Lactococcus lactis

Lc. lactis possesses an uptake system for the osmoprotectant GB, known as BusA/OpuA, linked with the ATP- binding cassette (ABC) superfamily of transporters. The system has high compatibility with GB and a lower one with proline. It is comprised of 2 nucleotide-binding domains (NBD) integrated into cystathionine-β-synthase (CBS) domains, forming the OpuAA subunit and 2 substrate binding domains embedded in transmembrane domains, constituting the OpuABC subunit (Mahmood et al., 2009). The osmotic stimulation of OpuA is based on regulating the on/off mode of the transporter, through (inter) mediate action of a protein module (CBS domains) with charged membrane surface. Its activation involves intensity levels of ionic strength, sensed by tandem CBS domains, found at the C- terminal end of OpuAA complex (Biemans-Oldehinkel et al., 2006). The negatively charged C-terminal tail coordinates the sensing of internal ionic strength. Briefly, below the intensity levels of ionic strength, the transporter is kept in an inactivate mode, while at higher medium osmolality, the osmosensing mechanism shifts the “electrostatically sealed mode” of the transporter to an “active” one.

BusR protein has been in the epicenter of intensive study due to its repressor character on the osmotically activated system, BusA, of *Lc. lactis*. Upon osmotic down-shock, BusR attaches the BusA promoter (BusAp) in a manner determined by the ionic concentration. In more detail, BusR reacts to hypoosmotic conditions, by forming a ternary structure with RNA polymerase, found at the promoter site. When cytoplasmic ionic strength increases, BusR detaches from BusAp, facilitating the initiation of busA operon transcription.

An osmosensitive phenotype in *Lc. lactis* subsp. *cremoris* has been described by Obis et al. (2001), having been associated with a limited capability of betaine uptake. This contrasting behavior with the rest *Lc. lactis* strains could be attributed to a deficiency of the busA operon or moderate expression or even restricted/poor activity of the BusA transporter.

Lactobacillus plantarum

As previously mentioned, LAB are characterized by restricted biosynthetic capabilities, making the transport of osmoprotectants from the surrounding media, critical for their survival under osmotic constraints. *Lb. plantarum* possesses a transport system, termed QacT (quaternary ammonium compound transporter), driven by ATP, with high affinity for GB and CA and a lower one for proline (Glaasker et al., 1998). As the GB uptake system is stimulated at elevated osmolality conditions until osmotic balance is achieved, so does the GB efflux from the cytosol, upon hypoosmotic circumstances. GB release from the cells include an accelerated initial phase, facilitated by a stress regulated mechanosensitive channel and a second slower one, enhanced by a carrier- like protein (Glaasker et al., 1996a; b). Therefore the up and down- regulation of GB transport system in *Lb. plantarum* is crucial for osmostasis control.

The addition of chlorpromazine, a cationic amphipath, reinforces the open state of MSCs and imitates osmotic down- shifts, by facilitating GB efflux from the cytosol (Glaasker et al., 1998). The release of osmoprotectants is accompanied with a lag time of 15 sec, when chlorpromazine is added, whereas it is extremely rapid upon osmotic down- shifts, highlighting the characteristics differentiating the QacT system from the common transport mechanisms.

Tetragenococcus halophila

T. halophila (formerly *Pediococcus halophilus*) is a moderately halophilic bacterium, characterized by the capacity to tolerate high salt concentrations. Sharing analogous biosynthetic attributes with other LAB, *T. halophila* cannot synthesize *de novo* effective compatible solutes, therefore it is strongly dependent on their presence in the defined media. Except from the compatible solute uptake system, activated under hyperosmotic conditions, *T. halophila* is the first lactic acid bacterium, in which the existence of a choline- GB pathway, under aerobic conditions, has been reported (Robert et al., 2000). Baliarda et al. (2003a) documented the presence of two GB accumulation systems, the former carrying GB only and the latter facilitating the transport of betaines, choline and carnitine. The identification of ButA protein from the osmotolerant *T. halophila* has been linked with the betaine choline carnitine transporter (BCCT) family, involving divergent osmoprotectant uptake systems, for instance BetL from *Listeria (L.) monocytogenes* and OpuD from *Bacillus (B.) subtilis*. Except from the osmoprotective role of GB on *T. halophila*, the exogenously supplied DMSA and DMSP (GB structural analogues) also relieve inhibitory effects of NaCl stress. In addition, presence of tetrahydropyrimidine ectoine in the surrounding media of the halophilic bacterium has been found to enhance its osmoprotection (Baliarda et al., 2003b).

Additional Lactic Acid Bacteria

Although the aid of compatible solutes like GB, CA and choline was previously described and highlighted for a variety of LAB, *Lb. bulgaricus* was not able to accumulate

those osmolytes under stressed conditions (Chun et al., 2012). In other words, GB and proline uptake system was not activated, which was associated with a lack of genes regulating the transport mechanism in the genome of *Lb. bulgaricus*. More analytically, *B. subtilis* uptake system, also known as OpuA, preferentially accumulates GB; however, the genes encoding the specific transport system were not identified in *Lb. bulgaricus*. The amino acids aspartate and alanine could counterbalance the osmotic suppression caused under NaCl stress.

Similar osmotic response was observed in *O. oeni*, the predominant bacterium of malolactic fermentation (MLF). GB accumulation system was not up-regulated, probably due to a lack of uptake mechanisms related to the BusA/OpuA- BusA/OpuC GB transporters (Le Marrec et al., 2007). Inability to concentrate choline was also reported, validating the absence of choline- GB pathway in *O. oeni*. Nevertheless, the exogenously added aspartate exhibited its osmoprotective role, restoring the ionic imbalance between cell's surroundings and cytosol.

As for *Streptococcus (Str.) mutans* UA159, resided in oral cavity, an *opc/opu* gene array was identified (Abranches et al., 2006). The specific gene complex, belonging to the Opu family of ABC transport systems, seems homologous with corresponding genes in *Str. agalactiae* as well as the OpuC transport mechanism of *L. monocytogenes*.

CONCLUSION

The response of some LAB with technological significance to osmotic changes has been studied to some extent. Current available data, although revealing, are based on a rather limited number of strains. Therefore it is practically impossible to assess strain diversity and include it to the already discovered differences between species. In addition, identification of the transcription factors that are activated by this environmental stimulus as well as their regulons is still to be explored. Taking into consideration the importance of an effective osmotic stress response, it is reasonable to expect our knowledge to expand within the next few years.

ABSTRACT

Nowadays consumers demand for healthier foods and for chemical free additives products. Lactic acid bacteria (LAB) have a generally recognized as safe (GRAS) status according to Food and Drug Administration Agency. Furthermore, they are an important source of bioactive compounds with wide applications in the food industry. Some of these compounds are *in situ* produced while others are *ex situ*. LAB have been used to produce fermented products since ancient times and the safety and sensory characteristics of these products rely on a diversity of metabolites produced *in situ* by LAB. In the last decades, the possible application of LAB metabolites as preservatives has increased; mainly bacteriocins, which were even approved worldwide. However, the use of LAB metabolites as additives is still emerging, particularly in the case of biosurfactants. These can exhibit emulsifying, antiadhesive and antimicrobial activity. The main objective of this chapter is to review the current status of the knowledge and possible applications of biosurfactants as additives for the formulation of foods.

INTRODUCTION

Biosurfactants are amphiphilic compounds produced by microorganisms, mainly bacteria and yeasts. They are multipurpose additives since they can reduce surface and interfacial

* Corresponding Author's Email: carmen@di.fcen.uba.ar.

tension, act as emulsifying, antiadhesive and antimicrobial agents. Furthermore, they are environmental friendly, biodegradable, and show low toxicity. Consequently, their search has attracted the attention in the last decades. Most studies were focused on bioremediation and few were done about the food industry, although the increasing demands for replacing synthetic additives by naturals (Nitschke & Costa, 2007).

Biosurfactants can be classified according to their chemical composition and microbial source. Regarding their chemical composition, some of them are low-molecular mass compounds while others are high molecular mass ones. The first group includes glycolipids, lipopeptides and phospholipids that are efficient for lowering surface and interfacial tension, the second ones are of polymeric nature and act as emulsions stabilizers (Nitschke & Costa, 2007).

Most biosurfactants are produced by bacteria belonging to *Pseudomonas*, *Bacillus*, *Acinetobacter* and by lactic acid bacteria (LAB). The latter, include different genera, particularly, *Lactobacillus*, which constitutes part of the indigenous flora of the gastrointestinal track of humans, and is generally recognized as safe. For this reason, its application is considered safe.

The main drawbacks from LAB biosurfactants are that they are less effective to reduce the surface tension, they have higher critical micelle concentrations (CMC), they are produced in lower amounts and finally, they are cell-bound being necessary an extraction process for their recovery (Nitschke & Sousa e Silva, 2018).

Regarding the chemical composition of biosurfactants produced by lactobacilli, they are glycolipids, glycoproteins, lipopeptides, glycopeptides or phosphoglycoproteins, independently of the strain and culture conditions used (Hajfarajollah et al., 2018).

The role of biosurfactants *in vivo* is still a matter of debate. One proposal is that they are implicated in the emulsification of water-insoluble substrates improving their absorption. Also, they are considered as components of cellular metabolism, motion and defense since they take part in cell adhesion to interfaces (Sharma et al., 2016).

Food products have pH values within the range of 3.0 to 7.0, they content salts that modify ionic strength and during processing and storage they are exposed to different temperatures. Therefore, the biosurfactant must be selected taking into account that it will have to be stable in the conditions of use. For example, Rodrigues et al., (2006 a) evaluated surface tension within the range of pH 4 to 10 for the crude and purified biosurfactant produced by *Streptococcus (Strep.) thermophilus* A. They found that the ability to reduce surface tension remained stable in the range studied but a purified fraction precipitated at pH 4, limiting its use in this condition.

Optimal conditions for production depend on the producing microorganism and also on the nature of biosurfactant. In most cases, the amount of biosurfactant released by *Lactobacilli* is maximum during the stationary growth phase (Velraeds et al., 1996; Golek et al., 2009). In the case of *Acinetobacter (Ac.) calcoaceticus*, biosurfactant production was directly associated with the growth of the microorganism (Desai & Desai, 1993). Furthermore, the C:N ratio seems to be a critical factor in the production of biosurfactants and a 1:1 ratio would be optimal (Bakhshi et al., 2018).

It is well known that one of the drawbacks for biosurfactant uses is the high cost of production and particularly, for LAB biosurfactants, their low productivity. For this reason, many investigations have been done looking for the conditions to optimize production. Moreover, alternatives culture media using renewable and low-cost raw materials such as

agricultural wastes were evaluated. For example, hemicellulosic sugars from vineyard pruning waste were successfully applied to obtain a glycolipopeptide with promissory emulsifying capacity from *Lactobacillus (Lb.) pentosus* fermentation (Vecino et al., 2015). Moreover, rice, wheat bran and straw were evaluated for biosurfactant production by *Lb. plantarum* subsp. *plantarum* PTCC 1896 and it was reported that only the rice bran hydrolysate was adequate as substrate for biosurfactant production (Bakhshi et al., 2018). Finally, biosurfactant production by *Lb. pentosus* using whey as culture media was assayed and compared to production using MRS and it was found that biosurfactant production was similar in both media. However, the strain did not growth well in the whey media, probably due to the lack of nutrients (Rodrigues et al., 2006 b). The satisfactory results of the use of wastes for biosurfactant production encourage the continuous search for the optimal conditions of production and the study of the structure–function relationship in food systems. According to Mouafo et al., (2018) a reduction of 30-50 % of production cost can be obtained by using alternative substrates.

Regarding the use of different culture media, it must be stressed that most of the biosurfactants are cell bound; consequently, their extraction from culture medium is necessary. After the incubation of LAB at selected conditions for production and centrifuging to remove the supernatant, bound to cells biosurfactant can be extracted by re-suspension in PBS and gentle stirring or by re-suspension in distilled water and extraction using an ultrasonic cell disintegrator. Use of phosphate buffer saline (PBS) together with gentle stirring is the most common procedure (Hajfarajollah et al., 2018).

Main biosurfactants can be applied as emulsifying, antiadhesive and antimicrobial agents as it will be discussed in the next sections. In addition to this, they can be used to control flat globules agglomeration, stabilize foams and improve bakery products texture (Nitschke & Costa, 2007). Finally, some recent studies proposed their use as antioxidant agents, for example, a lipopeptide from *Bacillus subtilis* exhibited good activity to scavenge free radicals (Nitschke & Sousa e Silva, 2018).

APPLICATIONS OF BIOSURFACTANTS AS EMULSIFIER AGENTS

Emulsions are colloidal dispersions of lipids and water that need the addition of a surfactant to lower the interfacial tension in order to decrease the superficial energy between the two phases. Different types of surfactants are used in the food industry, some of them are synthetic compounds and, as previously mentioned, there is a trend to replace them by natural products. There are a large number of excreted biosurfactants derived from *Pseudomonas* and *Bacillus* strains that have potential capacities to be used as emulsifiers, such as rhamnolipids, emulsan and liposan. However, their origin limits their use in the food industry. Therefore, the biosurfactants derived from LAB are an alternative option, although they are less effective in reducing surface tension of water than the former (Mouafo et al., 2018).

The potential application of biosurfactants as emulsifying agents is measured by their effectiveness in reducing superficial tension, in having low CMC and high emulsification capacity. Table 1 shows parameters of several biosurfactants obtained from LAB. Reductions of surface tension of water higher than 8 mN/m are considered as the minimum for a biosurfactant to be effective. Furthermore, CMC expresses the concentration which

corresponds to the minimum value of the surface tension that can be obtained with each compound. Important surface tension reductions (41.90 and 46.20 mN/m), low CMC (8 and 15 mg/mL) and high emulsification indexes (77.25 and 89.00% after 24 h) were observed with *Lb. delbrueckii* N2 using molasses or glycerol as substrates (Mouafo et al., 2018). Morais et al., (2017) extracted surface active compounds from *Lb. jensenii* P6A and *Lb. gasserii* P65 with potential application as bioemulsifiers in food (Table 1).

Biosurfactant production is not a simple matter. The extraction yields and structures are dependent on the right balance of culture media nutrients, microbial growth phase, and conditions of growth such as fermentation time, pH and temperature. These factors should be controlled to assure biosurfactant production with well-defined and consistent functionality and quality. Sugar cane molasses or glycerol were evaluated for biosurfactants production by *Lb. cellobiosus* TM1, *Lb. delbrueckii* N2, and *Lb. plantarum* G88. Mainly glycoproteins were obtained with molasses and glycolipids with glycerol indicating that biosurfactant composition is also substrate dependent. Yields obtained with both substrates were higher than those obtained with MRS broth whereas high surface tension reductions and emulsification indexes were observed with molasses as substrate (Mouafo et al., 2018).

In relation to microbial growth phase and growth conditions, Madhu and Prapulla (2013) observed that biosurfactant released by *Lb. plantarum* CFR 2194 was higher under stationary than shaking conditions and it was maximum after 72 h of fermentation showing a decrease of surface tension of 44.3 mN/m, a CMC of 6 g/L and high emulsification indexes against coconut and sunflower oils (Table 1). These emulsions were more stable than emulsions formed with hydrocarbons and they could be of interest for application in food formulations.

Regarding the effects of other additives and conditions used for biosurfactant production, Vecino et al., (2015) studied the effect of NaCl concentrations, time and temperature of extraction on emulsifying ability of the biosurfactant produced by *Lb. pentosus* through a Box-Behnken response surface methodology. The extraction was carried out at the beginning of the stationary phase, after 24 h of fermentation, when biomass concentration was at its maximum. All variables affected the ability of the biosurfactant to act as emulsifier being the most influential variables the time of extraction, followed by temperature, and salt concentration. The optimal conditions were 9 g/kg salt, 45°C and 120 min. From the chemical point of view, the biosurfactant extracted was a mixture of carbohydrate, protein and lipid in a combination of 1:3:6, respectively. Then, this biosurfactant was successfully used to stabilize a rosemary oil/water emulsion with most droplets diameter < 100 µm and which exhibited a creamy consistency. On the contrary, the same emulsion stabilized with polysorbate 20 was less consistent and more unstable.

Sharma et al., (2014) studied the effect of pH (4, 6, 7, 8 y 10), temperature (4, 22 y 37°C), NaCl concentration (4, 6, 8 y 10%), carbon and nitrogen sources on emulsification index of different biosurfactants produced by *Lactobacillus* strains isolated from milk samples. The decrease in salt level and temperature promoted an increase in emulsification index. Strains preferred yeast extract as nitrogen source instead of urea, and there was no marked preference between glucose and sucrose as a carbon source.

Table 1. Compilation of some uses of biosurfactants as emulsifier agents

LAB Strain	Substrate used for production	Emulsion formation	Assay performed and trends observed	Reference
<i>Lb. pentosus</i>	Hemicellulosic sugars from vineyard pruning waste	Rosemary oil/water emulsions	- CMC*: 2 mg/L (measured as surfactin equivalents, 25°C) - Relative emulsion volume of 55.5% after 24 h of emulsion formation Emulsions of water and rosemary oil stabilized with the biosurfactant were more stable than those stabilized with polysorbate 20.	Vecino et al., (2015)
<i>Lb. plantarum</i> subsp. <i>plantarum</i> PTCC 1896	Rice and wheat bran and straw	Canola oil emulsion	- Maximum emulsification index was 64.70% - Maximum emulsion stability was 97.73%	Bakhshi et al., (2018)
<i>Lb. delbrueckii</i> N2, <i>Lb. cellobiosus</i> TM1, <i>Lb. plantarum</i> G88	Sugar cane molasses or glycerol	Refined palm oil emulsion	- STR* ranged from 49.00 to 41.90 mN/m; - Emulsification index ranging from 41.81 to 81.00%. - CMC: 8 to 20 mg/mL	Mouafo et al., (2018)
<i>Lb. jensenii</i> P6A <i>Lb. gasserii</i> P65	MRS broth	Emulsification of several hydrocarbons and cotton, olive and sunflower oils.	For <i>Lb. jensenii</i> P6A: - STR to 42.5 mN/m - CMC: 8.58 mg/mL - Maximum emulsifying activity: at 5 mg/mL - Emulsification activity values ranged from 71 to 75% for cotton, olive, and sunflower oils For <i>Lb. gasserii</i> P65: - STR to 42.5 mN/m - CMC: 8.58 mg/mL - Maximum emulsifying activity: at 5 mg/mL - Emulsification activity values ranged from 71 to 75% for cotton, olive, and sunflower oils.	Morais et al., (2017)
<i>Lb. Plantarum</i> CFR 2194	MRS broth	Coconut and sunflower oils emulsions	- STR to 44.3 mN/m - CMC: 6 g/L - Emulsification index: 37.9% for coconut oil and 19.43% for sunflower oil. Coconut and sunflower oils emulsions were more stable than emulsions formed with hydrocarbons.	Madhu and Prapulla (2013)

Table 1. (Continued)

LAB Strain	Substrate used for production	Emulsion formation	Assay performed and trends observed	Reference
<i>Lb. helveticus</i> MRTL	MRS-Lac (glucose replaced by lactose)	Emulsification with kerosene	- STR to 39.5 mN/m - CMC: 2.5 mg/mL - Emulsification index of 65% Biosurfactant was stable at pH range (4.0-12.0), it was more effective at pH 7 and surface properties were kept after heat treatment at 125°C for 15 min. -Emulsion stability from 70.4 to 93.3% depending on growth media	Sharma and Saharan (2016)
<i>Lb. pentosus</i>	Residual stream after tartaric acid extraction from vinasses	Emulsification with kerosene		Salgado et al., (2013)
<i>Lb. coryniformis</i> ssp. <i>torquens</i> CECT 25600 <i>Lb. plantarum</i> A14 <i>Leuconostoc mesenteroides</i> <i>Lb. paracasei</i> ssp. <i>paracasei</i> A20	MRS-Lac Different nitrogen sources in MRSLac broth (peptone, meat extract, and yeast extract) on <i>L. paracasei</i> ssp. <i>paracasei</i> A20	_____	- STR from 69.6 to 50.0 mM/m after 8 h of fermentation for all strains. <i>Lb. paracasei</i> ssp. <i>paracasei</i> A20 showed the higher reduction. Higher biosurfactant production in presence of peptone and meat extract for <i>Lb. paracasei</i> ssp. <i>paracasei</i> A20, with a STR of 24.5 mN/m.	Gudiña et al., (2011)
Eight strains of <i>Lactobacillus</i> spp.	<i>Pendidam</i> (fermentative acid milk)	Emulsification with refined palm oil	- STR from 45.09 to 53.68 mM/m - Emulsification index from 10 to 56.80%	Mbawala and Mouafo (2012)
<i>Lactobacillus acidophilus</i> CECT-4179 (ATCC 832) <i>Debaryomyceshanseni</i> NRRL Y-7426	Synthetic hemicellulosic sugars Hemicellulosic vine-shoot trimming hydrolysates	_____	- STR of 24.5 mN/m <i>Lb. acidophilus</i> STR in synthetic sugars and 18 mM/m in trimming vine shoots. - Dilutions (biosurfactant extract volume/total volume) to achieve CMC were 0.138 for synthetic sugars and 0.152 for trimming vine shoots.	Portilla et al., (2008)
<i>Lactobacillus pentosus</i>	Hydrolysates of vine pruning waste	gasoline/water emulsions	Studied the effect of pH, temperature and salinity on surface-active properties. - STR from 53.8 to 69.3 mM/m - Emulsion volume up to 47.48% - Emulsion stability up to 100% Maximum emulsifying capacity and emulsions stability were achieved at temperatures below 30°C, salinity below 3%, and pH higher than 5.	Vecino et al., (2012)

*STR: Surface tension reduction, CMC: Critical Micellar Concentration.

Since most of chemical structure of biosurfactants contains proteins, the thermal stability is an important property to be studied. Producing a biosurfactant with high thermostability extends its range of application. Vecino et al., (2015) observed that as the production temperature increases, the emulsifying capacity of the biosurfactant obtained from *Lb. pentosus* increases, therefore, being thermostable makes it have better functionality. Bakhshi et al., (2018) extracted a water soluble extracellular high molecular weight α -glucan bound with protein, with high melting point (182.0°C) and high degradation temperature (211.74°C). Morais et al., (2017) evaluated the effect of pH, temperature (100°C) and salt concentrations (NaCl, KCl and NaHCO₃) on the activity of biosurfactants extracted from *Lb. jensenii* P6A and *Lb. gasseri* P65. They obtained stable emulsions after 60-min of incubation at 100°C, at pH 2–10, and after the addition of KCl and NaHCO₃.

APPLICATIONS OF BIOSURFACTANTS AS ANTIADHESIVE AGENTS

A large number of foodborne bacteria are capable of adhering to and forming biofilm on different surfaces, such as stainless steel, plastic, glass (Wang et al., 2014) and even food surfaces, like fruits and vegetables (Bilek et al., 2013). The adhesion of bacteria on surfaces compromises food safety, and produces food spoilage, generating huge economic losses (Van Houd & Michiels, 2010). Consequently, there is a focus of interest around the development of innovative techniques to overcome this issue.

One possible application of biosurfactants produced by LAB is as an antiadhesive agent (Table 2). It could be used as a surface conditioner, preventing the adhesion of microorganisms and the subsequent formation of biofilm, avoiding the use of synthetic disinfectants with considerable toxicity levels. For this reason, LAB surfactants present a great potential in food industry. Nevertheless, it is notorious that in most cases the applications studied are closely related with the biomedical area and used as conditioners of silicone rubber normally used in catheters and prosthesis (Rodrigues et al., 2004; Ceresa et al., 2015; Sharma et al., 2016). Furthermore, it was proved the anti-adhesion effect against strains isolated from voice prosthesis (Rodrigues et al., 2006, a), from the mouth and blood (Fracchia et al., 2010), uropathogenic bacteria (Velraedes et al., 1998) and skin pathogens (Vecino et al., 2018). To our knowledge only one study has reported the use of LAB biosurfactant as stainless steel conditioner, material commonly used in food industry (Meylheuc et. al, 2006), and none on the effects against film forming microorganisms isolated from food environments, nevertheless there is an expansion in the knowledge in these promising fields.

The genres of LAB biosurfactant producers showing antiadherent capability are *Lactobacillus*, *Lactococcus*, and *Streptococcus*. Many researchers have shown that biosurfactants produced by *Lactobacillus* strains are capable to reduce the adherence of bacteria to different surfaces. An early investigation on this subject has reported the ability for biosurfactant production of fifteen *Lactobacillus* strains and investigated further to determine their capacity to inhibit the initial adhesion of *Enterococcus* (*Ec.*) *faecalis* 1131 to glass.

Table 2. Compilation of some uses of biosurfactants as antiadhesive agents

LAB strain/source	Target m.o. for antiadhesive activity	Assay performed	Effect	Reference
<i>Lc. lactis</i> 53 / Nutricia (The Netherlands)	<i>S. epidermidis</i> GB 9/6, <i>Strep. salivarius</i> GB 24/9, <i>S. aureus</i> GB 2/1, <i>Rothia</i> (R.) <i>dentocariosa</i> GBJ 52/2B, <i>Candida</i> (C.) <i>albicans</i> GBJ 13/4A, <i>C. tropicalis</i> GB 9/9	Anti-adhesion assay in polystyrene 96 wells plate	Adhesion reduction of 70% for <i>S. aureus</i> GB 2/1 and <i>S. epidermidis</i> GB 9/6 at concentration 25g/L	Rodrigues et al., (2006 a)
<i>Strep. thermophilus</i> A / NIZO	<i>S. epidermidis</i> GB 9/6, <i>Strep. salivarius</i> GB 24/9, <i>S. aureus</i> GB 2/1, <i>R. dentocariosa</i> GBJ 52/2B, <i>C. albicans</i> GBJ 13/4A, <i>C. tropicalis</i> GB 9/9	Parallel-plate flow chamber on silicone rubber and image analysis	Adhesion reduction of 89-97% for bacteria and 67-70% for yeasts at concentration 3g/L	Rodrigues et al., (2006 b)
<i>Lb. helveticus</i> 1181 /Cheese industry	<i>L. monocytogenes</i> CIP103574, <i>L. monocytogenes</i> CIP104794, <i>L. monocytogenes</i> CIP103573 <i>L. monocytogenes</i> CIP78.39	Co-incubation assays on metallic supports	Adhesion reduction of 93.62–99.77% at concentration 5g/L.	Meylheuc, et al., (2006)

*MTT: 4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide.

This research showed that *Lb. acidophilus* RC14 and *Lb. fermentum* B54 were able to produce a biosurfactant, which reduced the deposition of *Ec. faecalis* by an average of 70% and the adhesion by an average of 77% (Velraeds et al., 1998). Those strains of *Lactobacillus* biosurfactant producers were two of many others found in the last decades capable to produce biosurfactants which reduced the adhesion of bacteria to surfaces. *Lb. paracasei* isolated in a Portuguese dairy industry produced a biosurfactant capable to reduce the adhesion of *Staphylococcus* (*S.*) *aureus* to polystyrene by a percentage of 72.0%, 62.1%, for *S. epidermidis* and *Strep. agalactiae*, respectively in a biosurfactant concentration of 25 mg/mL. However, a lower activity was observed for decreasing the adhesion of *Pseudomonas* and *Escherichia* strains, at the same biosurfactant concentration (Gudiña et al., 2010 a). On the other hand, biosurfactants produced by *Lb. helveticus* inhibit the adhesion of *Escherichia* (*E.*) *coli* ATCC 25922 in a 50.1% at a concentration of 25 mg/mL (Sharma & Saharan, 2016). Hence, the antiadhesive capability of a biosurfactant against a pathogenic strain is different according to the bacterium that is producing the biosurfactant and also the target of the bacterium which is desirable to control.

As previously commented, there are several studies reporting *Lactobacillus* strains as producers of biosurfactants, but there are few studies about the ability to produce biosurfactants by strains of *Lactococcus*. Three *Lactococcus* strains were reported as biosurfactant producers, *Lc. lactis* 53 (Rodrigues et al., 2004; Rodrigues et al., 2006 b), *Lc. lactis* CECT-4434 (Rodriguez et al., 2010; Souza et al., 2017), *Lc. lactis* (Saravanakumari & Mani, 2010), but only for *Lc. Lactis* 53 the anti-adhesive potential had been studied. According to Rodrigues et al., (2006 b), the biosurfactant produced by *Lc. lactis* 53 shown three fractions, isolated by hydrophobic interaction chromatography. All fractions shown antiadherent activity, but the best result was provided by the fraction A, inhibiting the adhesion to polystyrene of all microorganisms target even in a concentration of 5 mg/mL. The crude biosurfactant produced by *Lc. lactis* 53 has been also proved as conditioner of silicone rubber (Rodrigues et al., 2004). This study has been performed in a parallel-plate flow chamber equipped with a microscope allowing *in situ* observation and images analysis. In these experimental conditions, the surfactant adsorbed on the silicone rubber reduced the deposition rate above 90% for *S. epidermidis* GB 9/6, *Strep. Salivarius* GB 24/9, and *S. aureus* GB 2/1, the same percentage of reduction was reached for the cells adhering after 4h.

Some *Streptococcus* strains have been identified as producer of biosurfactants exhibiting anti-adherent activity. Rodrigues et al., (2006 a) studied the biosurfactant produced by *Strep. thermophilus* A, reporting a reduction of adhesion after 4 hours of 89-97% for bacteria and 67-70% for yeasts on silicon rubber, using the biosurfactant at a concentration on 3 mg/mL. Moreover, Van Hoogmoed et al., (2006), Busscher and Van der Mei (1997) have reported two strains of *Streptococcus* biosurfactant producers with antiadhesive activity. But all these studies were focused on biomedical applications.

It was demonstrated that not only the strain of the bacterium is responsible for the biosurfactant characteristics; also the method of extraction can change the anti-adherent properties of a biosurfactant. For example, when extraction of biosurfactants produced by *Lb. pentosus* and *Lb. paracasei* were done using phosphate buffer (PB), the adherence of *S. epidermis* and *Strep. pyogenes* were decreased in 57 and 69 % respectively. But, when extraction was done using PBS, the decrease in adherence was 38% and 52%, respectively (Vecino et al., 2018).

One emerging trend is the incorporation of anti-adhesive agents into the packaging material. According to Abdul et al., (2014), the addition of a biosurfactant produced by *Lb. rhamnosus* to a polyvinyl alcohol film prevented the biofilm formation of *S. aureus* and *Pseudomona (P.) aeruginosa*.

The main pathogenic bacteria related to the food industry that is of interest to prevent biofilm formation are *Listeria (L.) monocytogenes*, *E. coli (enteropathogenic strains)* and *S. aureus*.

Listeria monocytogenes is linked with many outbreaks and cause a food illness that presents a mortality rate of 25% worldwide (de Noordhout et al., 2014). It can be found in a high concentration in foods, especially ready-to-eat foods (Buchanan et al., 2017). It is capable to form biofilm even at refrigeration temperatures (Moltz & Martin, 2005) and can persist in food process environments for years (Hoelzer et al., 2015). For these reasons it is necessary to develop strategies to combat the adhesion of cells to surfaces and the subsequent formation of biofilm. So far, the effect of two biosurfactants produced each one by a *Lb. helveticus* strains were reported showing very promising results (Meylheuc et al., 2006; Sharma & Saharan, 2016). The biosurfactant produced by *Lb. helveticus* (Sharma & Saharan, 2016) at a concentration of 25 mg/mL, inhibited the adhesion of *L. monocytogenes* MTCC 657 and *L. innocua* ATCC 33090 to polystyrene in a percentage of 84% and 82%, respectively.

Escherichia coli is identified as responsible for outbreaks of foodborne illness (Greig & Ravel, 2009; Bélanger et al., 2015). It is a strong biofilm former that persists in the equipment of food industries (Yang et al., 2018), produced in presence of food residues (Dutra et al., 2018). Therefore, it is of interest to find approaches that prevent *E. coli* biofilm formation. Some researchers studied the use of LAB as inhibitors of adherence to surfaces for different *E. coli* strains (Gudiña et al., 2010 a, b; Madhu & Prapulla, 2013; Sharma et al., 2016; Vecino et al., 2018). The results by the time, present LAB as substances capable to produce a low degree in the adhesion of *E. coli* to polystyrene, been the highest reduction percentage scored of 56.78% using the biosurfactant produced by *Lb. plantarum* CFR 2194 in a concentration of 25 mg/mL, against the strain *E. coli* MTCC 108 (Madhu & Prapulla, 2013).

Staphylococcus aureus is well known as a foodborne pathogen, which produces enterotoxins that can poison food (Le Loir et al., 2003), form biofilm on surfaces used in food industries (Dutra et al., 2018) and under food-related stress conditions (Rode et al., 2007). Many researchers reported positive results for the anti-adhesive LAB properties against different *S. aureus* strains in two type of surfaces, polystyrene (Rodrigues et al., 2006 a, b; Madhu & Prapulla, 2013; Gudiña et al., 2010 a, b; Sharma et al., 2016; Vecino et al., 2018) and silicone rubber (Rodrigues et al., 2004; Sharma et al., 2016). In polystyrene, the highest inhibition of adhesion reported was 83%, conditioning the surface with a biosurfactant produced by *Lb. helveticus* in a concentration of 25 mg/mL, against the strain *S. aureus* ATCC 6538P (Sharma and Saharan, 2016). In silicone rubber, the initial deposition of *S. aureus* GB 2/1 was reduced in 90%, conditioning the surface with the biosurfactant produced by *Lc. lactis* 53 (Rodrigues et al., 2004). Even though LAB look to be great surface conditioners in polystyrene and silicon rubber, no results are reported for the effect of the adherence of *S. aureus* in common surfaces used in food industry such as stainless steel.

Regarding the spoilage bacteria, *P. aeruginosa* has the ability to form biofilm and exhibits several virulence factors coordinately by quorum sensing when it is contaminating foods (Viola et al., 2018). It is closely related with waterborne diseases, wet environments are

ideal for the formation and proliferation of biofilm, as different components of water systems (Walker & Moore, 2015). Some researchers studied the anti-adherence capability of LAB against the adhesion of *P. aeruginosa* to polystyrene surfaces, and all of them obtained positives results but with different degrees of inhibition (Gudiña et al., 2010 a; Sharma et al., 2016; Vecino et al., 2018). The best result was obtained using the biosurfactant produced by *Lb. paracasei* and extracted with phosphate buffer saline in a concentration of 25 mg/mL, obtaining an inhibition of 72% (Vecino et al., 2018). This degree of inhibition was higher than the previously reported values of 49% (Sharma et al., 2016) and 16.5% (Gudiña et al., 2010 a) for the same biosurfactant concentration.

According to results previously commented, there is a huge potential in the use of biosurfactants produced by LAB as anti-adherence agents. However, there are not many studies about the effective reduction of adhesion of many foodborne bacteria. The lack of these studies opens a door for novel investigations in the field of food microbiology.

APPLICATIONS OF BIOSURFACTANTS AS ANTIMICROBIAL AGENTS

The search for natural antimicrobials is of increasing concern to mitigate the development of antibiotics resistance against clinical pathogens and also to satisfy consumer demands for chemical additives free and healthier foods. Antimicrobials obtained from microbial sources present a huge potential due to their high biological activity and the possibility of production at low cost in an industrial scale.

The main advances in the knowledge of antimicrobial action of biosurfactantes were done in the field of biomedical sciences (Nitschke & Costa, 2007; Sharma et al., 2016). Conversely, they are very few research focused on the food industry.

Biosurfactants present antimicrobial activity; they exhibit action against virus, algae, bacteria, yeast and molds. Furthermore, several hypotheses are proposed to explain the mechanism of action: i) adhesion to cell surfaces damaging cell membrane integrity; ii) insertion of fatty acids from biosurfactant into cell membrane promoting changes in its composition and functionally; iii) ability to form pores in the membrane altering its functions (Sharma et al., 2016).

The main genera within LAB producing biosurfactants with antimicrobial activity was *Lactobacilli*. Different studies reported that they were able to inhibit the growth of bacteria and yeasts. Gram positive bacteria were more sensitive than Gram negative and yeasts were the more resistant. These trends were related to the fact that Gram negative present a polysaccharide layer in the external membrane which acts as a barrier to biosurfactant. In addition, yeasts present higher phospholipid content into the membrane which facilitates the interaction with biosurfactant (Mouafo et al., 2018).

Table 3 shows a compilation of biosurfactant producing LAB exhibiting antimicrobial activity. It can be observed that most of the strains were isolated from food. In addition, the target microorganisms evaluated were pathogens, in some cases isolated from medical uses. Finally, in all cases the activity was only tested *in vitro*.

Table 3. Compilation of some uses of biosurfactants as antimicrobial agents

LAB strain/source	Target m.o. for antimicrobial activity	Assay performed	Effect	Reference
<i>Strep. thermophilus</i> A/ Nizo (The Netherlands)	<i>S. epidermidis</i> GB 9/6, <i>Strep. salivarius</i> GB 24/9, <i>S. aureus</i> GB 2/1, <i>R. dentocariosa</i> GBJ 52/2B, <i>C. albicans</i> GBJ 13/4A, <i>C. tropicalis</i> GB 9/9 Isolated from explanted voice prostheses	Agar diffusion assay	Antimicrobial action depended on concentration. At 40 g/L all microorganisms were inhibited. Most sensitive was <i>C. tropicalis</i>	Rodrigues et al., (2006 a)
<i>Lc. lactis</i> 53 / Nutricia (The Netherlands)	<i>S. epidermidis</i> GB 9/6, <i>Strep. salivarius</i> GB 24/9, <i>S. aureus</i> GB 2/1, <i>R. dentocariosa</i> GBJ 52/2B, <i>C. albicans</i> GBJ 13/4A, <i>C. tropicalis</i> GB 9/9 Isolated from explanted voice prostheses	Agar diffusion assay	Antimicrobial action depended on biosurfactant fraction concentration.	Rodrigues et al., (2006 b)
<i>Lb. casei</i> 8/4/ Culture collection University of Warmia, Poland	<i>S. aureus</i> 11, <i>B. subtilis</i> , <i>Micrococcus (M.) roseus</i>	Agar diffusion assay	Antimicrobial action depended on incubation time.. Maximum activity was found after 18 h where all bacteria growth was inhibited	Golek et al., (2009)
<i>Lb. paracasei</i> / Portuguese dairy industry	<i>E. coli</i> , <i>P. aeruginosa</i> , <i>S. aureus</i> , <i>S. epidermidis</i> , <i>Strep. agalactiae</i> , <i>Strep. pyogenes</i>	Broth microdilution method and absorbance reading at 600nm	Crude biosurfactant showed antimicrobial activity against all tested bacteria	Gudiña et al., (2010 a)
<i>Lb. plantarum</i> CFR 2194 / kanjika	<i>E. coli</i> ATCC 31075, <i>E. coli</i> MTCC 108, <i>Salmonella typhi</i> , <i>Y. enterocolitica</i> MTCC 859, <i>S. aureus</i> F 722	Agar diffusion assay	Antimicrobial action depended on concentration. All bacteria assayed were inhibited except <i>S. typhi</i>	Madhu & Prapulla (2013)
<i>Lb. casei</i> MRTL3/ Raw milk	<i>S. aureus</i> ATCC 6538P, <i>S. epidermidis</i> ATCC 12228, <i>Shigella flexneri</i> ATCC 9199, <i>Salmonella typhi</i> MTCC 733, <i>P. aeruginosa</i> ATCC 15442, <i>B. cereus</i> ATCC 11770, <i>L. monocytogenes</i> MTCC 657, and <i>L. innocua</i> ATCC 33090	Agar diffusion assay	Crude biosurfactant inhibited all pathogens assayed	Sharma & Saharan (2014)
<i>Lb. agilis</i> CCUG31450/ Culture Collection of University of Gothenburg (Sweden)	<i>E. coli</i> , <i>P. aeruginosa</i> , <i>S. aureus</i> , <i>Strep. agalactiae</i> and <i>C. albicans</i>	Broth microdilution method and absorbance reading at 600nm	No antimicrobial activity was observed against <i>E. coli</i> and <i>C. albicans</i>	Gudiña et al., (2015)
<i>Lb. helveticus</i> / Yak milk cheese	<i>E. coli</i> ATCC 25922, <i>P. aeruginosa</i> ATCC 15442, <i>Salmonella typhi</i> MTCC 733 <i>Shigella flexneri</i> ATCC9199, <i>S. aureus</i> ATCC 6538P, <i>S. epidermidis</i> ATCC12228, <i>L. monocytogenes</i> MTCC 657, <i>L. innocua</i> ATCC 33090, <i>B. cereus</i> ATCC 11770	Broth microdilution method and absorbance reading at 600nm	Biosurfactant concentrations between 1.56 and 25 mg/mL promoted different degree of inhibition of all bacteria evaluated	Sharma & Saharan (2016)

Table 3. (Continued)

LAB strain/source	Target m.o. for antimicrobial activity	Assay performed	Effect	Reference
<i>Pediococcus acidilactici</i> / Artisanal milk cheese	<i>S. aureus</i> CMCC 26003	Broth microdilution method and visual evaluation of turbidity and time–kill assay	MIC was higher than 100 mg/mL and a 50 mg/mL affected the growth.	Yan et al., (2019)
<i>Lactobacillus acidophilus</i> , <i>L. pentosus</i> , <i>L. fermentum</i> , <i>L. plantarum</i> , <i>L. lactis</i> , <i>L. casei</i> / Fermented foods	<i>P. fluorescens</i> , <i>P. aeruginosa</i> , <i>E. coli</i> , <i>Salmonella typhimurium</i>	Agar diffusion assay	Biosurfactants obtained from <i>L. plantarum</i> inhibited all bacteria tested	Abdalsadiq Nagea & Zaiton (2018)
<i>Lactobacillus jensenii</i> P6A and <i>Lactobacillus gasseri</i> P65/ Women vaginal fluids	<i>E. coli</i> , <i>Klebsiella pneumoniae</i> , <i>Enterobacter aerogenes</i> , <i>S. saprophyticus</i> , <i>C. albicans</i> ATCC 18804, <i>C. krusei</i> ATCC 20298, and <i>C. tropicalis</i> ATCC 750	Broth microdilution method and visual evaluation of turbidity	No antimicrobial activity was observed against <i>C. krusei</i> and <i>C. tropicalis</i> . The rest of microorganisms tested were inhibited.	Morais et al., (2017)

Very few studies were done proposing the use of biosurfactants as antimicrobials compounds *in vivo*. For example, Abruzzo et al., (2018) evaluated successfully phosphatidylcholine based vesicles containing a biosurfactant produced by *Lb. gasseri* and econazole for the treatment of vaginal *Candida* infections. Mbawala et al., (2017) applied a crude surfactant extracted from a fermented milk to improve the microbial quality of yellow achu soap, a typical African meal. They used the crude surfactant as a dual agent, emulsifier and antimicrobial and they could decrease total aerobic and coliform populations. Also, a complete inhibition of *Salmonella* spp. and faecal streptococci was reached.

CONCLUSION

Regarding the attempts made to apply biosurfactants produced by LAB, the following facts can be remarked:

- The number of studies on this field has increased in the last years, especially in relation to medical uses. However, the cost is still a problem to solve since chemical surfactants are cheaper, even using agricultural wastes as substrates.
- In the food applications, up to now only one product, named Pre-liminate® is produced at an industrial scale, this formulation can be applied to surfaces in contact with food and it is designed to prevent biofilm formation.
- To increase food uses, *in vivo* studies must be performed in order to understand how the biosurfactants interact with other additives and/or food components. Also it is essential to know the sensorial impact of the biosurfactant and its stability during the food shelf life.
- In relation to the antimicrobial activity of biosurfactants, no information is available about their action on food spoilage microorganisms. It can be stressed that growth of spoilage microorganisms is responsible for high economic losses in the food industry.
- Studies about the interaction with other biosurfactants or with other additives in order to find synergic combinations are useful approaches to facilitate biosurfactant uses.

Outcomes shown herein highlight that biosurfactants from LAB present a huge potential and there are many unexplored areas that need to be studied in order to develop novel applications for the food industry.

ABSTRACT

Lactic acid bacteria (LAB) involve a diverse group of gram-positive bacteria that primarily produce lactic acid. For centuries LAB have been recognized as safe and employed for food processing due to their ability to control the adventurous microbiota in the elaboration of dairy products, vegetables, meats, coffee, cocoa, silages and fermented beverages; but also because of their contribution to the taste, flavor and texture. Moreover, probiotic LAB may offer health benefits by acting in the modulation of the immune system, helping to manage allergies and lactose intolerance; in addition to the prevention of gastrointestinal and urinary infections by reduction of pathogens. The ability of LAB to inhibit spoilage and pathogenic microorganisms is based on several mechanisms that include acidification, production of antimicrobials and competition for nutrients and adhesion niches. Antimicrobials include the lactic and acetic acids, but also a complex range of metabolites like hydrogen peroxide, diacetyl, antifungal short-chain fatty acids, pyroglutamic acid, as well as, antimicrobial peptides known as bacteriocins and antibacterial peptidoglycan hydrolases (PGHs). Bacteriocins refer to a diverse group of ribosomal antimicrobial peptides mainly active against closely-related and sensitive bacterial strains by formation of pores in the cytoplasmic membrane causing reduction of

* Corresponding Author's Email: pae@xanum.uam.mx.

microbial competitors. Among them, nisin and other bacteriocins have been applied in the food and pharmaceutical industry to control *Listeria monocytogenes* and *Staphylococcus aureus*. On the other hand, PGH are proteins capable to cleave the peptidoglycan cell wall of gram-positive and gram-negative bacteria, examples include lysostaphin and lysozyme, which are highly active against *Staphylococcus aureus*. The objective of this chapter is to offer an overview of the characteristics and applications of bacteriocins and peptidoglycan hydrolases as part of the beneficial metabolites produced by LAB.

INTRODUCTION

Lactic acid bacteria can be found in several habitats such as the gastrointestinal tract of animals and humans, as well as in the microbiota in several foods. This microbial group comprises gram-positive, facultative anaerobic, non-spore forming, non-motile and acid tolerant bacteria from the genus *Aerococcus*, *Alloiococcus*, *Carnobacterium*, *Enterococcus*, *Lactobacillus*, *Leuconostoc*, *Oenococcus*, *Pediococcus*, *Streptococcus*, *Tetragenococcus*, *Vagococcus* and *Weissella*. Those are low G+C (31 - 49%) and belong to the *Lactobacillales* order within the *Firmicutes* phyla. Besides, the *Bifidobacterium* genus with a high G+C content (58 - 61%) belongs to the *Actinobacteria* phylum (Khalid 2011; Giraffa, 2014; Fraqueza, 2015). LAB are also classified into homofermentative and heterofermentative according to the end products derived from the glucose metabolism into lactic acid, carbon dioxide, ethanol or acetic acid.

LAB have been safely used for centuries and therefore recognized as safe (GRAS and QPS qualified presumption of safety) by the FDA and EFSA authorities. They are widely employed as starter cultures in the food industry to accelerate ripening or to control de adventitious microbiota for elaboration and preservation of several fermented foods. Applications include the processing of fermented milks, chesses, vegetables, meats, coffee, cocoa, silages, sourdough bread and wine, among others. But, LAB also contribute to the taste, flavor and texture as a result of several reactions, including lipolysis, proteolysis, conversion of lactose in citrate and various aromatic compounds, such as diacetyl, acetoin, acetaldehyde and acetic acid. In addition, their proteolytic activity induces the accumulation of small peptides and free amino acids that are further transformed into alcohols, aldehydes, acids, and esters responsible for the flavor profile and organoleptic characteristics of fermented foods. Some LAB can produce a range from 10 to > 2,000 kDa exopolysaccharides that not only confer protection to the cell producer, but may improve texture and mouthfeel of yogurt and other low-fat milk products. Moreover, LAB are industrially involved in the production of some macromolecules and enzymes (Gad, Abdel-Hamid & Farag, 2014; Özogul & Hamed, 2016).

A number of LAB strains have been used as probiotics and considered desirable members of the intestinal microbiota, including *Lactobacillus*, *Bifidobacterium*, *Propionibacterium* and *Enterococcus* strains present in foods and in dietary supplements. Other reported health benefits associated to LAB probiotics include an antihypertensive effect, reduction in the cholesterol level, antioxidant effect, relief of the allergy symptoms, decrease in dental caries and protection against colon cancer. Such, as the production of the antihypertensive angiotensin-converting enzyme produced through the proteolytic system of *Lb. helveticus*, *Lb.*

acidophilus and *Lb. delbrueckii* (Giraffa, 2014; Sharma et al., 2014). Therefore, LAB are also recognized to improve healthiness due to their influence on the immune system and reduction of pathogens, in addition to their positive role in the control of some infections during pregnancy, antibiotic-derived diarrheas and intestinal inflammation, or to alleviate some allergies, as well as, to deliver vaccines and other metabolites directly in the gastrointestinal tract (Sharma et al., 2014).

Among all these beneficial metabolites produced by LAB, a major attribute is their ability to inhibit spoilage and pathogenic microorganisms based on the competition, their great acid tolerance and production of several antimicrobials (Khalid, 2011; Giraffa, 2014). These antimicrobial metabolites include lactic and acetic acids, ethanol, hydrogen peroxide, diacetyl, antifungals (short chain fatty acids derived from lipolysis reactions), and antimicrobial peptides known as bacteriocins and other antibacterial proteins like peptidoglycan hydrolases (PGHs) (Khalid, 2011; Giraffa, 2014; Sharma et al., 2014). The last two metabolites, bacteriocins and PGHs constitute an important and viable alternative to antibiotics and food grade preservatives due to their antimicrobial action against several pathogens including multi-antibiotic-resistant strains (Álvarez-Cisneros & Ponce-Alquicira 2018).

BACTERIOCINS

Most bacteria may produce antimicrobial proteins, which can be ribosomally synthesized or non-ribosomally synthesized (Chikindas et al., 2018). Bacteriocins produced by LAB constitute a heterogeneous group of ribosomal antimicrobial peptides, varying in size, structure and specificity. They are active against closely related species found in the same environmental niche where the producer strain is protected by the presence of specific immune proteins (O'Connor et al., 2015). Genes responsible for their production and immunity are usually grouped in the same cluster (Perez, Zendo and Sonomoto 2014; O'Connor et al., 2015; Chikindas et al., 2018; Field, Ross & Hill, 2018). Several studies have demonstrated the potential of LAB bacteriocins to be applied for food preservation, or an alternative antibiotics in the clinical area, mainly due to their tolerance to high temperatures and their activity over a wide pH range against spoilage microorganisms and pathogens such *Bacillus*, *Clostridia*, *Listeria (L.) monocytogenes* and methicillin-resistant *Staphylococcus (S.) aureus* and vancomycin-resistant *Enterococci* at concentrations lower than that for conventional antibiotics (Schneider et al., 2006; Alvarez-Cisneros et al., 2010; Martin-Visscher et al., 2011; Perez, Zendo & Sonomoto, 2014). Generally, LAB bacteriocins are considered food-grade because the GRAS or QPS status of most bacteriocinogenic strains (Perez, Zendo & Sonomoto, 2014). Bacteriocins do not impart color or flavor and are easily degraded by the proteolytic enzymes, especially those formed in the pancreas (trypsin and chymotrypsin) and gastric tract (pepsin) that makes them safe for human consumption, thus minimizing the opportunity of target strains to interact and develop resistance (Zacharof & Lovitt, 2012). However, bacteriocins may have some limiting factors such as a restricted inhibitory spectrum, lack of purification protocols and/or acceptable recovery yields, a producer strain classified with non GRAS recognition, and/or the development of bacteriocin-resistant bacteria. Nonetheless, the ribosomal origins of bacteriocins enable their

bioengineering either to modulate their physicochemical properties and improve their stability in food systems, or to enhance the inhibiting activity and spectra; in addition, their heterologous expression in other hosts could be a valid alternative to increase yield or induce multiple bacteriocin production (Alvarez-Cisneros et al., 2011; Field, Ross & Hill, 2018).

Bacteriocins are diverse, some authors such as Chikindas et al., (2018) point that the primary action of bacteriocins are for signaling and repelling at their low concentration that occurs in natural environments; for instance, nisin (produced by *Lactococcus lactis*) and subtilin (from *Bacillus subtilis*) participate as modulators for their own production and transport (Balciunas et al., 2013). But, mutacin V produced by *Streptococcus* (*Strep.*) *mutants* can act as lytic agent against the producer cell to facilitate the exchange of genetic material with non-lysed competent cells. While, other bacteriocins can inhibit the quorum sensing at sub-MBC (minimal bactericidal concentration) to prevent the settle down and biofilm formation of competitors. In contrast, when bacteriocins are employed at MBC or at higher levels they can induce permeation and formation of pores in the cytoplasmic membrane and/or interfere with the cell division process and with other biological functions thus inactivating sensitive cells (Chikindas et al., (2018).

A restriction in the use of bacteriocins may be the presence of innate or acquired resistance observed in some susceptible strains. In particular, *L. monocytogenes* has shown resistance when exposed to high levels of nisin (> 10 fold MBC), as well as resistance to class IIa bacteriocins due to changes in the cell membrane properties. Also, *Bacillus* (*B.*) *cereus* can produce the enzyme nisinase capable to degrade the bacteriocins nisin and subtilin. However, no significant data is available for the resistance mechanism and the resistance can be solved by changing the pH, the type of carbohydrates or the salt concentration of the environmental growth (Ahmad et al., 2017; Balay, Gänzle & McMullen, 2018).

The number of reported bacteriocins is continuously growing, but to date the BACTIBASE, an open-access database (<http://bactibase.pfba-lab-tun.org>), contains calculated or predicted physicochemical and structural properties of 230 bacteriocins produced by 206 gram-positive bacteria and 19 gram-negative, being LAB the predominant bacteriocin producers. The database allows a better comprehension of the bacteriocins functionality towards the development of applications and classification by the use of tools such as similarity, sequence alignment, physicochemical profile, hidden Markov Models and structure prediction. In addition, the BAGEL4 webserver (<http://bagel4.molgenrug.nl/>) allows the meta-genomic DNA search for bacteriocins and post-translationally modified peptides (RIPPs) providing databases and BLAST (basic local alignment search tool) for the core peptide databases.

Bacteriocin Classification

There are several classifications of bacteriocins, mainly based in their post-translationally modification through biosynthesis and transport to the extracellular media, as well as, on their mode of action and structure. Most bacteriocins are synthesized as an inactive precursor peptide precursor having an N-terminal leader peptide, attached to the C-terminal core peptide that is removed by proteases to yield the mature bacteriocin. The leader peptide usually serves as a recognition sequence for biosynthetic enzymes; also serves to modulate

the enzyme–substrate interaction for the post-translational modification (PTM) of the inactive pre-peptide that is later transported to the cell surface and transformed into the active peptide. The genetic determinants for bacteriocins production consist of less than 21 genes and their biosynthesis greatly differs, as some bacterial strains may produce more than one bacteriocin in addition to the production of PGH's (Acedo, et al., 2018).

The regulation system for the bacteriocin production is composed of an inducing peptide or pheromone–activating factor, the transmembrane histidine kinase and a response regulator. The inducer peptide is synthesized in the ribosome at low levels as a pre-peptide, which is then cleaved and secreted extracellularly by a carrier. At certain threshold concentrations the response phosphorylation receptor further activates the bacteriocin transcription. Lantibiotics (Class I) bacteriocins such as nisin act as pheromones or signal-involved membrane proteins that regulate their own production and transport; while accessory proteins induce the translocation for Class II bacteriocins (Balciunas et al., 2013).

The first bacteriocin classification scheme was proposed by Klaenhammer (1993) who defined four classes:

- Class I Lantibiotics (< 5kDa membrane-active peptides containing unusual amino acids as lanthionine, β -methyl-lanthionine and dehydrated residues);
- Class II [< 10 kDa heat-stable non-lanthionine containing membrane-active peptides with three sub-groups: IIa *Listeria* active peptides (with a consensus sequence in the N-terminal of Tyr-Gly-Asn-Gly-Val-Xaa-Cys- and a leader peptide GG), IIb complexes consisting of two leader GG peptides and IIc thiol-activated peptides];
- Class III for large heat-labile proteins and,
- Class IV for complex bacteriocins with a lipid or carbohydrate moiety.

Later, Cotter, Ross and Hill (2005) proposed the elimination of larger proteins from the bacteriocin classification arguing that bacteriocins should be referred as antimicrobial peptides, proposing the following classification:

- Class I for those bacteriocins subjected to an enzymatic PTM that was sub grouped according to their structure into twelve groups (MccC7-C57, lasso peptides, linear-azole, lantibiotics, linaridins, proteusins, sactibiotics, patellamide-like cyanobactins, anacyclamide-like cyanobactins, thiopeptides, bottromycins and glycocins).
- Class II included the unmodified or cyclic bacteriocins with five subgroups (IIa pediocin PA-1-like, IIb, IIc, IId and IIE peptides).
- Class III or “bacteriolysins” for thermo-labile high molecular weight peptides.

Recently, novel bacteriocins have been reported with the emerging of genome tools applied for the screening of published LAB genomes, resulting in 785 putative bacteriocin gene clusters, which also contain new RPPs different from the previously known bacteriocins. Therefore, a modification in the classification for most LAB bacteriocins was proposed by Alvarez-Sieiro et al., (2016). Class I resulted more diverse with six RPP subclasses, Class II comprises four subclasses and Class III for unmodified bacteriocins > 10 kDa with bacteriolytic and non-bacteriolytic activity (Table 1). Furthermore, Acedo et al.,

(2018) presented an overview of the structural variety of bacteriocins and their interactions with receptors and possible modes of action.

**Table 1. Classification for bacteriocins from LAB
(modified from Alvarez-Sieiro et al., 2016; Acedo et al., 2018)**

Class	Subclasses
Class I Heat stable < 10 kDa Posttranscriptional modified peptides (RIPPs)	Class Ia. Lanthipeptides (types I, II, III ¹ , IV ¹)
	Class Ib. Head-to-tail cyclized or circular peptides
	Class Ic. Sactibiotics ²
	Class Id. Linear azo(in)e-containing peptides (LAPs)
	Class Ie. Glycocins
	Class If. Lasso peptides ²
Class II Heat stable < 10 kDa Unmodified peptides Leader peptide GG	Class IIa. Pediocin-like linear (YGNGVXCXXXXCXV conserved at N-terminus)
	Class IIb. Two peptides
	Class IIc. Leaderless
	Class IId. Non pediocin-like, single-peptide
Class III Thermo-labile >10kDa	Bacteriolysins
	Non-lytic
	Tailocins (phage tail-like) ²

¹Types III and IV do not have known antimicrobial activity.

²None reported LAB bacteriocins, but putative clusters have been identified *in silico*.

However, many other bacteriocins are under study and some of the criteria used to classify bacteriocins are not fully applicable, such as the enterocins because they have common characteristics to more than one of the currently described bacteriocins classes or subclasses (Alvarez-Cisneros et al., 2011). For example, hemolysin from *E. faecalis* belongs to the lanthibiotic group (Class I), but its activity depends on the joint action of two peptides (Class IIb). Also enterocin P could be included in Class IIc because it is secreted by a pre-peptide translocase, but it has the YGNGV consensus sequence typical of Class IIa. Therefore, Franz et al., (2007) proposed a specific classification for enterocins that includes four main classes: lanthibiotic enterocins (Cass I), non-lanthibiotic enterocins (Class II), cyclic enterocins (Class III) and large proteins (Class IV). Class II was subdivided into three subclasses: the pediocin family of enterocins (IIa), enterocins synthesized without a leader peptide (IIb) and linear enterocins that do not belong to the pediocin family (IIc). Likewise, Ahmad et al. (2017) presented two schemes of classification, one based on the bacteriocin physicochemical properties, and other based on the presence of consensus sequence motifs claiming to include > 70% of the known bacteriocins.

Class I Bacteriocins

Class Ia of lanthipeptides or lantibiotics are small heat stable peptides that undergoes PTMs resulting in the formation of lanthionine (Lan), β -methyl-lanthionine (MeLan) and other unusual dehydrated amino residues. Serine and threonine residues go a two-step process that involve an enzymatic dehydration forming dehydroalanine (Dha) and dehydrobutyrine (Dhb), followed by a Michael-type condensation with the thiol-group of a neighboring cysteine residue to the β -carbon of Dha or Dhb forming a Lan or MeLan internal rings, that impart resistance to proteases (Acedo et al., 2018). Then the modified pre-peptide is transported and activated to the extracellular environment. The leader peptide for lantibiotics

have a conserved FNLD box with helical structure essential for the ring formation through the action of a cyclase enzyme, such as the NisC cyclase for nisin (Abts et al., 2013). Nisin A produced by *Lactococcus (Lc.) lactis* ssp *lactis*, lacticin 3147-A1 and lacticin 3147-A2 from *Lc. lactis* are the best studied subtype I and II from the Class Ia. The mechanism of action for most lantibiotics relies on the binding to the lipid II, a universal receptor and the main subunit transporter of peptidoglycan from the cytoplasm to the cell wall. Thereby, bacteriocins Ia block the proper cell wall synthesis that leads to the cell death. In particular, nisin A binds to Lipid II by its N-terminal rings forming a complex of eight lantibiotic bacteriocins molecules with four lipid II molecules with two dependent-concentration modes of action. At high levels, nisin A triggers the process of membrane insertion and pore formation, which leads to rapid cell death; but at low concentration, cell wall synthesis is repressed (Cotter, Hill & Ross, 2005.; Breukink & De Kruijff, 2006; Alvarez-Cisneros et al., 2011).

The head-to-tail circular, Class Ib bacteriocins, includes a group of RiPPs whose N- and C-termini are linked by a peptide bond. This group has recently attracted the attention because of their wide inhibitory action and their remarkable stability to proteases and heat treatments (Borrero et al., 2011; Grande-Burgos et al., 2014; O'Connor et al., 2015; Perez, Zendo & Sonomoto, 2018). Up to date, fourteen circular bacteriocins have been described and sub-divided in two groups according to their biochemical characteristics (Table 2).

Table 2. Classification and examples of circular bacteriocins (modified from Grande-Burgos et al., 2014; Perez, Zendo and Sonomoto 2018)

Group	Name	Producer strain
Group i (Highly cationic peptides with predicted pI > 9)	Carnocyclin A	<i>Carnobacterium maltaromaticum</i> UAL307
	Garvicin ML	<i>Lc. garvieae</i> DCC43
	Leucocyclin Q	<i>Leuconostoc (Leuc.) mesenteroides</i> TK41401
	Lactocyclin Q	<i>Lc.sp</i> QU12
	Enterocin AS-48	<i>Ec. faecalis</i> UGRA10
	Uberolysin	<i>Strep. uberis</i> 42
	Amylocyclin	<i>B. amyloliquefaciens</i>
	Circularin A	<i>Cl. beijerinckii</i> ATCC 25752
	Enterocin NKR-5-3B	<i>Ec. faecium</i> NKR-5-3
	Pumilarin	<i>B. pumilus</i> B4107
Group ii (Hydrophobic cationic peptides with predicted pI < 7)	Gassericin A	<i>Lbgaseeri</i>
	Butyrvibriocin AR10*	<i>Butyrvibrio fibrisolvens</i>
	Acidocin B	<i>Lb. acidophilus</i> M46
	Plantaricyclin A	<i>Lb. plantarum</i> N326

*negatively charged, predicted pI 3.88.

The biosynthesis of circular bacteriocins involves three stages: the cleavage of the leader peptide, circularization and extra-cellular secretion. The biosynthetic gene cluster includes a series of five to seven genes encoding for the precursor peptide, a cationic and hydrophobic immunity protein, an ABC transporter (composed by an ATPase and a membrane protein involved in the protein secretion that also confers partial immunity), and a membrane protein that participates in the circularization. The leader peptides for these bacteriocins are heterogeneous in size and sequence (ranging from 2-48 residues) with a non-clear role in the biosynthesis process but essential for the precursor peptide folding and interaction with processing enzymes. The dehydration and cyclization are catalyzed by the bifunctional

enzyme LanM, which has an N-terminal dehydratase domain and a C-terminal cyclase domain. LanM phosphorylates Ser/Thr, the resulting phosphate ester is eliminated to form Dha/Dhb (Acedo et al., 2018). Although the mode of action of most circular bacteriocins has not yet been elucidated, their antimicrobial action relies on their high net charge that facilitates their interaction with the negatively charged bacterial cell membrane causing non-selective ion channels, leaking of ions, dissipation of the membrane potential and eventually the cell death (Cebrián et al., 2012; Perez, Zendo & Sonomoto, 2018). Recent reports for the Enterocin AS-48 suggest a two stage mode of action, based on an electrostatically approach of the inactive water-soluble dimer towards the cell membrane followed by dissociation and insertion into the lipid bilayer and establishment of electrostatic and hydrophobic interactions with the monomeric bacteriocin (Cebrián et al., 2015; Perez, Zendo & Sonomoto, 2018).

Other Class I are the sactipeptides (Class Ic) that are described as sulfur-to- α -carbon-containing peptides. Examples include the subtilisin A produced by *B. subtilis* with high activity against *Clostridium (Cl.) difficile* and thurincin CD produced by *B. thuringiensis*, but only putative clusters have been identified in silico for LAB. Besides, the linear azol(in)e-containing peptides (Class Id) are composed by various heterocyclic rings of thiazole and methyl-oxazole derived from cysteine, serine and threonine residues. Being the streptolysin S produced by *Strep. pyogenes* the most representative, but also described as to potent cytolytic toxin and virulence factor (Wessel, 2005). Moreover, the Glycocins (Class Ie) are bacteriocins that contain glycosylated residues such as Glycicin F produced by *Lb. plantarum*, or the enterocin F4-9 from *Enterococcus (Ec.) faecium*. Finally, the lasso peptides (Class If) are RiPPs with an amide bond between the first residue in the core peptide chain and a negative charged residue in positions 7 to 9 generating a ring that includes de C-terminal. These bacteriocins display antimicrobial, antiviral and anti-carcinogenic activities as the Microcin J25 produced by *Eacherichia (E.) coli*, but non-reported bacteriocins from this type are produced by LAB (Alvarez-Sieiro et al., 2016).

Class II Bacteriocins

Class IIa pediocin-like bacteriocins are heat stable (< 10 kDa) and particularly active against *Listeria*. Their structure is characterized by a cationic and heat stable peptides lengthen from 37 to 48 amino acid residues, with isoelectric points (pI) varying from 8.3-10. The N-terminal contains two cysteine residues joined by disulfide bridges and a conserved YGNGVXCXXXXCXV motif. The C-terminus is less conserved and participates in the target cell specificity. The gen cluster is plasmid encoded and contains four genes such as the structural *pedA*, the immunity *pedB*, the *pedC* and *pedD*, which encode an ABC transporter and accessory proteins for pediocin PA-1. Other IIa bacteriocins include the enterocins such as the *Ec. faecium* MXVK29 that shows accessory genes (*entK*, *entR* and *entT*) adjacent to the structural and immunity and inducer genes. The leader peptide from most Class II bacteriocins poses a highly conserved double glycine motif that serves as recognition signal for the bacteriocin production and secretion; it can also be constitutively produced or regulated by a quorum sensing system. The mode of action comprises three steps: (1) link with the mannose phosphotransferase system (Man-PTS) receptors, (2) insertion into the cytoplasmic membrane and (3) hydrophilic pore formation that induces dissipation of proton motive force, the subsequent acceleration of ATP consumption to restore the proton motive force that leads to the cell death. However, the target membrane composition plays a role for the proper bacteriocin insertion and the final pore formation and allows the exit of ions,

amino acids and other essential molecules. Pediocin PA-1 (pediocin AcH) is the most studied IIa bacteriocins produced by *Pedococcus (Ped.) acidilatici* and *Lb. plantarum*, respectively; other examples include leucocin A, acidocin A, mesenterin and sakacin P. Those bacteriocins show antagonistic activity against several spoilage and pathogen microorganisms, including *L. monocytogenes*, *S. aureus* and *Cl. perfringens* (Alvarez-Cisneros et al., 2011; Balciunas et al., 2013; Alvarez-Sieiro et al., 2016; Escamilla-Martínez et al., 2017; Ríos-Colombo, Chalón & Navarro, 2018).

Class IIb bacteriocins require the presence of two complementary peptides, at about equal quantities, that work together for their antimicrobial action forming a membrane-penetrating helix-helix structure causing membrane leakage in sensitive bacteria, such as the lactococcin G produced by *L. lactis*, the lactacin F produced by *Lb. johnsonni* and plantaricins S and T produced by *Lb. plantarum*. Although, some individual peptides can present antimicrobial activity with synergistic action like for thermophilin 13 produced by *Strep. thermophilus*, as well as, plantaricins A, E/F, J/K and W produced by *Lb. plantarum* strains. Their synthesis is regulated by at least five genes, organized in one or two operons, containing two structural genes codifying for the pre-bacteriocins, in addition to immunity, ABC transporter and accessory proteins. Their synthesis is regulated by a quorum sensing system that involves an induction factor, a membrane protein histidine kinase and response regulators. However, both two-peptide-lantibiotic and non-lantibiotic have been reported, such as the enterocin W a two-peptide-lantibiotic produced by *Ec. faecalis* NKR4-1 (Barbosa et al., 2016; O'Connor et al., 2015).

There are several reports for leaderless IIC bacteriocins conformed by one, two or more peptides, in general they are cationic with high pI values. Examples include the single peptide LsbB from *Lc. lactis* BGMN1, enterocin Q from *Ec. faecium* L50, Enterocin K1 from *E. faecium* EnGen0026, Aureocin A53 from *S. aureus* A53, Lactacin Q from *Lc. lactis* QU5, weissellicin Y and M both from *Weissella hellenica* QU13, among others. In addition to the two-peptide enterocin L50 produced by *Ec. faecium* L50 and the multi-peptide garvicin KS from *S. aureus* A70. The IIC leaderless bacteriocins are synthesized without an N-terminal leader peptide; they do not undergo any PTMs and become active after translation, but self-immunity and the secretion mechanisms remain unclear for these bacteriocins. However, Miljkovic et al., (2016) revealed that expression of LsbB requires the presence of a complete transcription terminator located downstream of the *lsbB* gene. On the other hand, the production of weissellicin Y and M has a nutrition adapted control; while the production of enterocin L50 seems to be regulated by temperature within the range of 16 - 32°C. In relation to their mode of action, they do not require receptor molecules to form huge-pore-like structures (HTP) that cause leakage of large intracellular components lately inducing cell death (Alvarez-Sieiro et al., 2016; Perez, Zendo & Sonomoto, 2018).

Class IID or non-pediocin-like bacteriocins refer to unrelated single linear bacteriocins with different structures and mechanisms of action. Examples include lactococcin 972, lactococcin A and enterocin B, among others (Alvarez-Sieiro et al., 2016).

Class III Bacteriocins

Class III includes heat labile antimicrobial proteins with high molecular weight (> 10 kDa) with bacteriolytic and non-bacteriolytic activity. Most LAB bacteriolysins manifest their antimicrobial activity by cleaving the peptidoglycan cross-links of the target cell wall and fall into the peptidoglycan hydrolases (PGHs) group described in another section of this chapter.

On the other hand, the non-lytic bacteriocins execute their antimicrobial action interfering with some biological functions that finally leads to the inactivation of sensitive cells. Examples include the dysgalactin produced by *S. pyogenes* that inhibits the sugar uptake by interfering with the phosphotransferase systems (PTS) glucose and mannose causing membrane leakage of small molecules. As well as, caseicin from *Lb. casei* that inhibits the biosynthesis of DNA and proteins (Alvarez-Sieiro et al., 2016). Tailocins comprise large multiprotein complexes that take the shape of nanotubes larger than one million Da, resembling the tail structure of bacteriophages and causes cell death by inserting themselves into target membranes; examples include the pyocin produced by *Pseudomonads aeuroginosa* and diffocin from *C. difficile*, but no tailocins produced by LAB have been reported (Acedo et al., 2018).

Bacteriocin Applications as LAB Beneficial Metabolites

There is a worldwide demand for natural and safe products, with use of natural preservatives in combination of clean and environmentally-friendly processing technologies. From this point of view, LAB bacteriocins offer an important area of interest as they are recognized as natural and safe antimicrobials, especially those capable of inhibiting the growth of spoilage and foodborne pathogens, as well as methicillin-resistant *S. aureus* and vancomycin-resistant *Enterococci* at concentrations lower than that for conventional antibiotics. Bacteriocins differ from antibiotics in several aspects, first they are primary metabolites with a less complex biosynthetic mechanisms in comparison to the secondary metabolites antibiotics; most bacteriocins possess a narrow inhibitory activity by the action at the membrane and/or cell wall, they are active at nano- or micro-molar range, are sensible to proteases and temperature, do not alter color, taste or odor and present relatively low toxicity for eukaryotic cells, therefore they can be used for food preservation and therapeutics. In contrast, antibiotics are only approved for therapeutically use, have a broad spectrum, with activity at micro- to milli-molar range either inhibiting the synthesis of the cell wall or the cytoplasmic membrane, blocking the protein synthesis or the DNA copying processes or altering the metabolism that also may affect eukaryotic cells (Perez, Zendo & Sonomoto, 2014; Alvarez-Cisneros & Ponce-Alquira, 2018).

López-Cuellar, Rodríguez-Hernández & Chavarría-Hernandez (2016) published a ten years review of the LAB bacteriocin application, reporting a database of 429 papers and 245 patents between years 2004 to 2015 around the world. Articles were further classified by application topics, 29% were related to food preservation; 37% focused on biomedical applications for alternative treatment of systemic, oral, stomach, vaginal and respiratory infections, contraception, cancer, skin and personal care; 25% for bio-nanomaterials and packaging materials and 9% for their veterinary use. While patents were classified by the same application topics including also their production, purification and molecular modifications; 31% patents focused on biomedical uses, 29% on food preservation, 5% on veterinary applications, and 29% for production-purification processes and recombinant molecules. The application of bacteriocins include several strategies, such *in situ* by the direct inoculation of a LAB bacteriocinogenic strains as starters in fermented products, or *ex situ* by the addition of a purified or semi-purified bacteriocin as an additive, as well as, the

incorporation of a previously fermented product that contain bacteriocin-producer strain as an ingredient and immobilized bacteriocins into packaging film surfaces. But most industrially produced and commercially available purified or semi-purified bacteriocin preparations include nisin, pediocins, and carnocyclin A (Silva, Silva & Ribeiro, 2018).

Figure 1. Representation of the nisin A structure with the Lan (A-S-A) and MeLan rings (Abu-S-A), dehydroalanine (Dha) and dehydrobutyryne (Dhb). Arrows indicate the amino acid substitution sites for natural variants (F, Q, Z, U, U2, P and H) and the semi-synthetic nisin V (Modified from Shin et al., 2016 and Campion et al., 2013).

Nisin

The Class Ia bacteriocin nisin is the most studied bacteriocin; it has been recognized as safe and approved as natural food preservative by the Joint Food and Agricultural Organization/World Health Organization (FAO/WHO) since 1969. The United States Food and Drug Administration (FDA) also approved nisin in 1988 as well as the European Food Safety Authority (EFSA) with the number E234. It has been commercially used in several countries with differences in their level and application to inhibit the growth spoilage gram-positive bacteria, especially *Bacillus*, *Clostridium* and *Listeria* on meat, dairy and vegetables. The most known brand is Nisaplin™ (2.5% Nisin A), but some other commercial presentations, include nisin alone or in combination with other bacteriocins and/or other natural antimicrobials that can be found from Danisco and Chr Hansen, among other companies. There are eight natural nisin variants (A, F, Q and Z produced by *Lactococcus lactis* strains, as well as the U, U2, P and H variants produced by *Streptococcus* strains) along with several semi-synthetic nisin variants (Shin et al., 2016). Nisin A contains 34 amino acid residues with five internal ring structures generated by PTMs. The N-terminal domain contains one Lan and two MeLan rings linked through an intermediate flexible hinge region to the C-terminal containing two intertwined rings (Figure 1). The N-terminal domain binds to the pyrophosphate moiety of lipid II and facilitates the pore formation by the C-terminal domain, thus interfering with the cell wall biosynthesis and the cell membrane permeation (Campion et al., 2013). Nisin Z differs from nisin A in one amino acid residue at position 27 with an asparagine instead a histidine and possess higher solubility. Nisin F has two amino acid substitutions at positions 27 and 30; while nisin Q has four substitutions at positions 15, 21, 27 and 30. All of them are highly active against *S. aureus* and *L. monocytogenes* and other gram positive foodborne bacteria. Variants U and U2 are produced by *Strep. uberis*, in their structure contain nine and ten amino acid substitutions in comparison to nisin A. Nisins H and

P were detected from *Strep. hyointestinalis* and *Strep. gallolyticus* subsp *pasteurianus*, respectively.

The combination of nisin with other antimicrobials and the semi-synthetic variants have demonstrated an increased inhibitory activity against other non-food bacteria such as multidrug resistant pathogens such methicillin-resistant *S. aureus* (MRSA), vancomycin intermediate and heterogeneous *S. aureus*. However, semi-synthetic o bioengineered variants such as nisin V have shown an enhanced activity with therapeutic potential and great thermal stability and solubility, active against *Shigella*, *Pseudomonas* and *Salmonella* species (Campion et al., 2013; Shin et al., 2016).

Pediocin PA-1

Among the Ila bacteriocins, pediocin PA-A is the most studied due to its great ability to permeabilize the membrane of *L. monocytogens*, *S. aureus*, as well as, *Pseudomonas* and *E. coli*. It is thermally stable in a wide pH range, produced by *Pedococcus* spp and resistant to heating and freezing (Schneider et al., 2006; Silva, Silva & Ribeiro, 2018). Commercial pediocin presentations include ALTA® (Kerry Bioscience), MicroGard™, Fargo 23® (Quest International) and Bactoferm F-LC® (combination of pediocin and sakacin by Chr. Hansen) mostly recommended for preservation of dairy and meat products (López-Cuellar, Rodríguez-Hernández & Chavarría-Hernandez, 2016).

Carnocyclin A

Carnobacterium maltaromaticum UAL307 that was isolated from fresh pork, produces the class Ib bacteriocin Carnocyclin A, a circular 60 residues peptide that forms anion selective channels in the lipid membrane. This bacteriocin with the commercial brand Micocin® (Griffith Laboratories) has been approved for vacuum packaged meat products in United States, Canada Costa Rica, Colombia and Mexico against *Listeria monocytogenes*; but carnocyclin can also inhibit *E. coli*, *Pseudomona aeruginosa* and *Samonella* Typhinurium (Martin-Visscher et al., 2008; 2011; Marketwire, 2011; Koné et al., 2018).

Application of Bacteriocins to Improve Food Preservation

There are several reports in relation to the use of bacteriocins for food preservation as these antimicrobial peptides can prevent the growth and transmission of spoilage and food borne pathogens by preventing the biofilm (surface-associated microbial communities) formation on surfaces, retarding the microbial growth and the biogenic amines formation during refrigeration, thus increasing the shelf life of foods while maintaining their nutritional and sensory qualities (Galié et al., 2018; Özogul & Hamed, 2018). Bacteriocins can be used in several forms, either produced *in situ* by the incorporation of LAB bacteriocinogenic strains in fermented and non-fermented foods, or produced *ex situ* by addition of a previously purified or concentrated bacteriocin in a food grade substrate. The use of bacteriocinogenic LAB for food preservation is attractive due to their GRAS status that fulfill the consumer's demands for minimally processed foods and ready-to-eat (RTE) products free from artificial additives. The producer strain can serve as a starter or be added as an additional protective culture. Protective bacteriocinogenic strains may grow and produce bacteriocins during

refrigeration storage in which may be part of the predominant microbiota, thus inhibiting the proliferation of pathogenic bacteria especially during temperature abuse conditions in meat and dairy products. The use of multiple bacteriocins or multibacteriocinogenic strains seems to be more effective for food preservation; as reported by Mills et al. (2017) that generated a double bacteriocin producer (*Lc lactis* CKS2775) via conjugation capable to produce nisin and lacticin providing a multihurdle approach to control pathogens in cheese.

Other food applications include immobilized preparations applied on the surface of the food product or included in antimicrobial active packaging, coatings and nanocomposite films. For instance, Martinez-Murillo et al., (2013) incorporate nisin into whey protein isolate film with antibacterial activity against *Listeria innocua* (ATCC 33090) and *Brochothrix thermosphacta* (NCIB10018) (Khaneghah et al., 2018).

Immobilized bacteriocins are more stable as the carrier protects them from inactivation due to variations in the pH, prevention of their interaction with enzymes and other food components (including lipids and other proteins). Furthermore, immobilization can regulate the bacteriocin release into the food system (Balcinas et al., 2013). Bacteriocins have been encapsulated using several methodologies including liposome formation, coextrusion, spray coating, fluid-bed coating, complex coacervation and formation of silver nanoparticles, alone or in combination with other antimicrobials, preserving their antimicrobial action (Calderón-Oliver, et al., 2017).

The thermal stability of bacterial spores is a major problem in the food industry; LAB bacteriocins may be involved as part of a hurdle processing due to their anti-spore activity against dormant spores and/or germinated spores. The bacteriocins nisin, enterocin-AS48 (produced by *Ec. faecalis* A-48-32), lacticin 3147 (produced by *L. lactis* subsp. *lactis* DPC3147), plantaricin TF711 (produced by *Lb. plantarum* TF711), as well as, the bacteriolysins pentocin L and pentocin S (produced by *Ped. pentosus* L and S) have shown inhibitory action against spores of *Cl. perfringens*, *Cl. sporogenes*, *Cl. botulinum*, *Cl. difficile* and *B. cereus* with differences in their mode of action. In particular nisin reduces the thermal stability of bacterial spores and prevents the outgrowth of survival spores in heat threatened milk and apple juice. Similar data was observed in food models subjected to non-thermal food preservation processes such as high-pressure processing and pulsed electric field, or in systems of bacteriocins combined with plant extracts, sucrose fatty esters and potassium sorbate (Egan et al., 2016).

Bacteriocins in Human Health and Skin Care

Penicillin resistant *S. pneumonia*, vancomycin resistant enterococci (VRE), MRSA, intermediate and heterogeneous *S. aureus*, *Strep. pneumoniae* and *Cl. difficile*, among other bacteria represent a major medical risk all around the world, for their incidence in bacteremias, pneumonia and postsurgical infections, especially for immunocompromised patients. Those bacteria can be adhered or implanted on the surface of medical devices or damaged tissues in the form of a biofilms, thus causing chronical infections. Bacteriocins show a promising alternative to traditional antibiotics, their primary difference is their activity against closely related bacteria. In particular, Nisin A in combination with conventional antibiotics, lysozyme and lactoferrin can promote a synergistic effect against MRSA and

reduce the biofilm formation. Therefore, this bacteriocin and other natural and bioengineered lantibiotics such as NVB302 (semi-synthetic derivate from actagardine), microbisporicin, mutacin 1140 (produced by *Strep. mutants*) and the lantibiotic lactacin are examples of bacteriocins under clinical trial to treat hospital related infections, including drug-resistant infections, as an option to substitute or decrease the use of antibiotics.

Shin et al., (2016) present a review of the biomedical applications of nisin as a promising tool to improve human health, including the treatment of oral infections and cancer. For instance, the development of an antimicrobial nanofiber wound dressing containing nisin was used to reduce the colonization of MRSA and accelerate healing with non-adverse histological effects (Heunis, Smith & Dicks, 2013). Other applications include the topical nisin application to treat mastitis and reduce the staphylococcal count in the breast milk of nisin treated woman. Moreover, this bacteriocin has a synergistic action with poly-lysine and sodium fluoride for the prevention of planktonic and biofilm forms of the cariogenic bacteria *Strep. mutants*, and other gram-positive and gram-negative oral colonizing bacteria, as well as, an anti-biofilm effect on saliva without causing cytotoxicity to human oral cells. In addition, nisin has a potential to reduce periodontal disease by inhibiting *Ec. faecalis* (frequently present in infected teeth root canals) and for the prevention of oral candidiasis caused by *Candida albicans*, a prevalent pathogen that cause mucosal fungal infections.

Cancer is characterized by the dysregulated growth of abnormal cells, usually threatened by chemo- or radiotherapy and surgery with the concomitant detrimental of normal cells and severe affectation to the patients. Nisin and other bacteriocins such pyocin, colicin S4, defensin, pediocin, microcin may play a role for the treatment of cancer because of their activity against various types of cancer (Shin et al., 2016; Baidara, Korpole & Grover, 2018). In particular the use of nisin A in low concentrations (2.5%) showed an antitumor potential in head and neck squamous cell carcinoma (HNSCC) *in vitro* and *in vivo*, but higher concentrations of a combination of nisin Z and P (95%) had greatest level of apoptosis in HNSCC cells and decreased their proliferation demonstrating the potential of nisin as an anticancer agent (Kamarajan et al., 2015). Also the combination of nisin with conventional cancer drugs such doxorubicin potentiated the effectiveness against skin carcinogenesis (Preet et al., 2015). Recent data demonstrates the anti-carcinogenic effect of nisin due to the selective toxicity on melanoma cells, as well as, on gastrointestinal, hepatic and blood cancer cell lines (Lewies et al., 2018; Goudarzi et al., 2018).

Bacteriocins such as lactacin and fermenticin HV6b are potential spermicidal agents that induce reduction in the motility of human spermatozoa or sperm tail damage when used at high levels. In addition, other bacteriocins produced by *Ped. pentosaseus* SB83, *Ec. faecium* and *Lb. rhamnosus* can inhibit pathogenic vaginal bacteria such *Gardnerella vaginalis*, *Prevotella bivia*, *Bacteroides*, *Peptostreptococcus* and *Mobiluncus* spp (López-Cuellar, Rodríguez-Hernández & Chavarría-Hernandez, 2016).

There are several products containing bacteriocins from probiotic LAB bacteria to prevent and treat skin diseases, including external signs of aging, acne, rosacea, bacterial and yeast infections, psoriasis and dermatitis. All these applications derive from the bacteriocin contribution to the modulation of the skin microflora, and their action in the immune system and reduction of inflammatory processes. Examples include saivaricin, nisin, mersacidin, lactacin and leucocin A (López-Cuellar, Rodríguez-Hernández & Chavarría-Hernandez, 2016).

Bacteriocins in Veterinary and Agriculture

Antibiotics are commonly used in livestock and aquaculture for the treatment of bacterial infections as a prophylactic method to prevent bacterial diseases in healthy animals; they are also used as growth promoters to improve feed conversion and body-weight gain. This issue has become one of the main safety problems worldwide and several organizations such as the WHO, the FDA and EFSA, have raised awareness to stop using antibiotics in healthy animals, in order to reduce the emergence of antibiotic-resistance bacteria strains that could be potentially transmittable to humans and to preserve the effectiveness of antibiotics. The antibiotic-resistance can take place when microorganisms are continuously exposed to sublethal doses of antibiotics as a result of an adaptation process (Álvarez-Cisneros & Ponce-Alquicira, 2018). Therefore, there is an urgent need for novel antimicrobials that can be used for animal production with low development of resistance, where bacteriocins are of great interest mainly because of their antagonism against *Cl. perfringens*, enterotoxigenic *E. coli*, *Campylobacter jejuni* and *Salmonella enterica* that can affect both animal and human health, as well as, against *Streptococcus suis* a zoonotic agent that causes economic losses for swine production. In addition the administration of bacteriocinogenic strains, such as *Lb. salivarius* can help to modulate the gastrointestinal microbiota of healthy pigs reducing the levels of gram-negatives and the presence of opportunistic pathogens thus improving the meat microbial quality (Lagha, Hass, Gottschalk & Greiner, 2017).

PEPTIDOGLYCAN HYDROLASES (PGHS)

Peptidoglycan Structure

The peptidoglycan (PG) is a hetero-polymer of glycan backbones crosslinked by peptides forming a mesh-like layer in the bacterial cell wall. It is responsible for the rigidity and shape of bacterial cells; it is also involved in the bacterial resistance mechanisms to antibiotics, immune responses, phage susceptibility, serological behavior and protects against osmotic lysis, among others. The cell wall of gram-negative bacteria contains less than 10% PG. But for gram positive the PG content varies from 30-70% showing structural variations that may be considered a criterion for bacteria differentiation. In addition, the PG layer is highly dynamic showing structural changes during the cell growth and cell division processes (Meroueh et al., 2006; Bourhis & Werts, 2007; Wang & Shaevitz, 2013; Sharma et al., 2016).

The glycan backbone is made of alternating units of *N*-acetylglucosamine (NAG) and *N*-acetylmuramic acid (NAM) linked by β -1,4 glycosidic bonds. The peptide subunits contain four and occasionally five alternating L- and D- amino acids residues joined to the lactyl group of the NAM units. In general, L-alanine is directly bound to the NAM, followed by two amino acid residues with three functional groups (D-glutamic acid or threo-3-hydroxyglutamic [Hyg] at position 2) attached to an L-diamino acid at position 3, and a final D-alanine residue at position 4. But in some cases an additional L-alanine is also present at the C-terminus forming a penta-peptide subunit. The peptide subunit for most Gram-positive bacteria presents a L-Lysine residue at position 3, while a meso-diaminopimelate (mDAP) occurs for gram-negative and some gram-positive such as *Listeria*. Structural modifications give

rise to more than 100 different PG variants arranged into types A and B according on their peptide cross-linkage. The free amino group of the L-diamino acid residue (at position 3) directly participates in the cross-linkage to the D-alanine carboxyl group at (position 4) of an adjacent peptide subunit for the PG type A. In the case of PG type B the cross-linkage involves an inter-peptide bridge consisting of 1-7 glycine residues (Schumann, 2011).

Characteristics of Peptidoglycan Hydrolases

The enzymes capable of hydrolyze the PG cell wall promoting cell lysis, are known as peptidoglycan hydrolases (PGHs) and found in several organisms, including animals, plants, bacteria and viruses. Their synthesis is highly regulated, from their transcription to the posttranslational level in order to prevent the cell lysis (Kelly & Bayles 2003; Vollmer et al., 2008). PGHs have an important role as they participate in different phenomena of lysis, either to lyse host cells or to re-model the cell wall during growth and division (Bustamente, et al., 2012). Bacterial division results from the combination of membrane constriction with expansion and remodeling of the cell wall. For many bacteria, the cell lysis is a natural part of the life cycle and, in some cases, is useful to eliminate damaged cells within the population (Regulski et al., 2012; Høltje & Tuomanen, 1991; Smith, Blackman & Foster, 2000). PGHs represent a novel class of antimicrobials, as they can act selectively in the rapid killing of pathogenic bacteria without affecting the normal microbiota; also present low toxicity, moderate inhibition by the host immune response and low probability of developing resistance. All these features result of great interest for their biotechnological and pharmacological exploitation for food preservation and for the treatment of drug resistant infections (Bustamente, et al., 2012).

The activity of the PGHs also generates rotational products that serve as signaling molecules for the recognition of bacteria by other organisms and, in some bacteria, for the induction of β -lactamase that may provide resistance to β -lactam antibiotics. In addition, these hydrolases are also responsible for the autolysis under certain conditions. Most PGHs present a specific activity for each glycoside and amide bridges in the peptidoglycan (Vollmer et al., 2008). Although the PGHs physiological functions include the regulation of cell wall growth, the replacement of peptidoglycan during growth, the separation of daughter cells during cell division, it is difficult to assign a function other than a PGHs, because many bacteria have a high number of hydrolases with redundant roles, as they are able to break covalent bonds in sacs of peptidoglycan or their fragments (Høltje & Tuomanen, 1991; Smith, Blackman & Foster, 2000; Heidrich et al., 2001). Some specialized hydrolases enlarge the pores in the peptidoglycan in a temporal and controlled way, allowing the insertion of multiprotein complexes in the cellular sheath (pili, flagella, secretion systems), or split the PG during sporulation or germination of spores (Vollmer et al., 2008; van Heijenoort 2011; Høltje 2013; Maxime et al., 2018).

It has been proposed that some PGHs cooperate with other enzymes splitting the existing PG polymer allowing the insertion of new material, but the direct evidence for such a mechanism has not yet been proven. The role of PGHs involved in the cell separation and autolysis has been reported. Little is known about the cellular function of those PGHs involved in the maturation of PG, which includes the regulation of the length of the chains of

glycans and peptides, as well as the degree of cross-linking. In a very general way, PGHs functions include regulating the availability of PG precursors, PG maturation, septum splitting, cell separation and autolysis (Höltje & Tuomanen, 1991; Höltje, 1998; Smith, Blackman & Foster, 2000; Vollmer et al., 2008; van Heijenoort, 2011; Maxime et al., 2018).

Figure 2. Representation of the of peptidoglycan (PG) structure showing the N-acetylglucosamine (NAG) and N-acetylmuramic acid (NAM) subunits linked by β -1,4 glycosidic bonds and the glycine inter-peptide bridge for PG type B. Also the sites of peptidoglycan hydrolases (PGHs) action are presented for muramidases, glucoamidases, amidases and endopeptidases (Modified from Sharma et al., 2016,; García-Cano, 2013).

Classification of Peptidoglycan Hydrolases

The PGHs are widespread in bacteria and also known as autolysins classified according to the cleavage site. The three main classes include: (1) the glucosidases that fragment the glycan backbones; (2) the amidases or peptidoglycan amidases (*N*-acetylmuramyl-*L*-alanine amidases) that hydrolyze the amide bond between NAM and the N-terminal *L*-Alanine residue, thus separating the peptide subunits from the glycan backbone; and (3) the peptidases (endopeptidases and carboxypeptidases) that act within the PG peptide side chains (Figure 2).

Specifically, the glucosidases consist of *N*-acetyl- β -D-glucosaminidases, lysozymes and lytic transglycosylases. The first is an endo-glucoamidase that catalyzes the hydrolysis of the glycosidic bond between NAG and adjacent monosaccharides in different oligosaccharides such as PG, chitin and other N-glycans. These enzymes have a catalytic domain and one or more associated substrate-binding domains (CBDs), such as one to six LysM motifs generally located at one end of the protein, that bind directly to the PG thus affecting the substrate binding and the hydrolysis efficiency. The latter two glucosidases are known as *N*-acetyl- β -D-muramidases or muramidases that hydrolyze the β -1,4-glycosidic bonds between the NAM and NAG residues of PG. The resulting product from the lysozyme action is a terminal reducing NAM residue; while the lytic action of transglycosylases induces a

transglycosylation reaction resulting in the formation of 1,6-anhydro ring in the NAM residue.

The PG amidases or *N*-acetylmuramyl-*L*-alanine amidases hydrolyze the amide bond separating the peptide subunits from the glycan backbone. They are members of the bacterial autolytic systems and carry a signal peptide in their N-terminal site that allows their transport across the cytoplasmic membrane; while bacteriophage PG amidases are endolysins with no signal peptides (Vollmer et al., 2008). On the other hand, the peptidases that hydrolyze the amide bonds between amino acids in the PG, according to their specificity are endopeptidases (cleaving bonds within the peptide chain) or carboxypeptidases (removing the C-terminal amino acid). These PGHs are also named DD-peptidases, when cleaving between two D-amino acid residues, and LD- or DL- peptidases if the hydrolysis takes place between an L- and D- amino acid residues (Ghuysen, Tipper & Strominger, 1966; Layec, Decaris & Leblond-Bourget, 2008; Vollmer et al., 2008; Reith & Mayer, 2011; Johnson, Fisher & Mobashery, 2013; Johnson & Klaenhammer, 2016; Sharma et al., 2016).

Applications of Peptidoglycan Hydrolases as LAB Beneficial Metabolites

There is an increased interest in the study of natural antimicrobials that help to fight bacterial infections and the presence of opportunistic fungi. As they are associated with high mortality rates due to the emergence of antibiotic resistance. In this sense, PGHs are considered valuable alternatives or complements of the classic antifungal agents to fight infection by fungi (Delattin et al., 2017; Owen et al., 2018). On the other hand, multidrug-resistant strains are becoming more frequent and represent one of the main causes of morbidity and mortality. For this reason, new strategies are urgently needed to combat multi-drug-resistant pathogens. In this scenario, PGHs represent a valuable alternative as antibacterial agents due to its unique property of breaking the cell wall peptidoglycan of fungi, as well as, gram-positive and gram-negative bacteria with a low incidence to induce resistance; therefore they may replace or be used in combination with antibiotics (Sharma et al., 2016; Kashani et al., 2017).

PGHs may inhibit spoilage bacteria and food pathogens. In recent years lysozyme has been used as a natural antimicrobial, approved as a preservative in foods in USA and other countries. Its main applications have been in the prevention of gram-positive contamination in cheese and control of bacterial activity in wine. Another example is the lysostaphin active against *Staphylococcus aureus*, important pathogens in the food industry. But there is a wide range of PGHs which are being studied and that arise as an important alternative to combat a broad spectrum of bacteria, both gram-positive and gram-negative bacteria, which could be used as natural agents to fight against food-borne diseases (Callewaert et al., 2011; Carrillo et al., 2014).

Food Applications of Peptidoglycan Hydrolases

The two most studied PGHs in the food industry are lysozyme and lysostaphin. Lysozyme is a naturally occurring N-acetylmuramidase in both the animal and plant kingdoms that plays an important role in the natural defense mechanism and discovered by Alexander Fleming in 1922. Many researchers have described various biological activities of this

protein, including its antibacterial activity against gram-positive bacteria and harmless to human cells. However, their antibacterial spectrum has reached some gram-negative bacteria if their outer membrane is disrupted prior to exposure through thermal, chemical or enzymatic modifications, genetic mutations and synergistic effects with other compounds. It has been used by plants and animals as a natural defense mechanism against pathogenic bacteria and it is allowed as a food additive. For instance lysozyme is used in casings and cooked RTE meat and poultry products with the GRAS Notice No. 000064 given by the USDA.

Lysostaphin (also classified as a Class III bacteriocin) has been highlighted as a next-generation agent for the treatment against *S. aureus*, one of the main pathogens transmitted by food and nosocomial infections around the world, that causes diseases such as endocarditis, pneumonia and toxic-shock syndrome, among others (Kadariya, Smith & Thapaliya, 2014). Lysostaphin is a Zn^{2+} dependent endopeptidase with a molecular mass of ~ 27 kDa, a PI of 9.5 and a pH optimum of 7.5, also classified as bacteriocin. It consists of two domains (Figure 3), the N-terminal responsible for the catalytic activity of Gly-Gly bonds, and a C-targeting domain (CWT) that specifically binds to the pentaglycine bridge of the PG cell wall of *S. aureus* and *S. epidermidis* (Ojha et al., 2018; Tossavainen et al., 2018).

This PGH is produced by *S. simulans*, which represents a main concern for their use in the food industry. Therefore, lysostaphin has been cloned and expressed in various heterologous systems including BAL. For instance, food-grade lysostaphin has been produced in *Lc. lactis* and *Ped. acidilatici* using the NICE (Nisin-controlled gene Expression) system at industrial scale (Mierau et al., 2005; García-Cano et al., 2015).

PGHs have been proposed as a tool to prevent bacterial diseases transmitted by foods, which are associated with high morbidity, death and economic losses (Fischetti 2010). These hydrolytic enzymes could inhibit the growth of *E. coli* (including the pathogenic serotypes), *L. monocytogenes* (a ubiquitous bacteria that can cause abortion in pregnant women and other serious complications in children and elderly), *Salmonella enterica* serovar Typhimurium (which can cause massive outbreaks and even death in children and elderly), and *S. aureus* (Galié et al., 2018). Recently, several PGHs have been evaluated during the cheese manufacture, where the presence of non-starter BAL contribute to the development of desirable flavor characteristics and to the quality and safety of the final product due to the production of autolysins (Cibik & Chapot-Chartier, 2004; Aldrete-Tapia et al., 2018). Although few autolysins produced by the *Lactobacillus* genus have been characterized; the autolysin AclB produced by *Lb. casei* was purified and fully characterized. AclB was recognized as a species-specific cell separating enzyme responsible for the cell separation of *Lb. casei* after cell division, which helps to accelerate cheese ripening (Xu et al., 2015), in advantage with other autolysins such as the LytF produced *B. subtilis* as that only contributes synergistically to the cell separation (Margot, Pagni & Karamata, 1999; Xu et al., 2015). Some other autolysins could be applied in a similar way to improve food fermentations, such as the autolysin Acm2, required for cell separation in *Lb. plantarum* and *Lc. lactis* (Palumbo et al., 2006). There are also reports on the PGH endopeptidase activity for the surface layer (S-layer) of *Lb. acidophilus* against the cell wall of some bacteria. The S-layer is a bifunctional array of proteins or glycoproteins that overlay the cell surface of several *Eubacteria* and *Archaea*. The S-layer proteins are directly in contact with the bacterial environment and involved in surface phenomena such as bacterial co-aggregation, adhesion, protection and recognition or as carriers of virulence factors (Gerbino et al., 2015). The S-layer reported for *Lb. acidophilus* ATCC 4356 is composed of a single protein (protein S_A) of

~ 45 kDa, with endopeptidase activity against the cell wall of *Salmonella enterica*, *E. coli* and *Micrococcus luteus*. Therefore this S-layer proteins may in theory be use to prevent the growth of food spoilage microorganisms (Prado-Acosta et al., 2008; Hynönen & Palva 2013; Meng et al., 2015). Other similar PGHs like the Msp1/p75 produced by the probiotic *Lb. rhamnosus* GG that was initially reported as an anti-apoptotic and growth-promoting of intestinal cells, also shows PGH activity with D-glutamul-L-lysyl endopeptidase specificity for daughter cell separation of *Lb. rhamnosus*. In addition thirteen PGHs were detected in *Lb. casei* BL23 where the Lc-p75 was identified; this protein is the homolog of the previously mentioned Msp1/p75. Both PGHs are attached to the cell wall and secreted in the culture supernatant, which also have been confirmed being responsible for the cell wall lysis of different food deteriorating microorganisms (Claes et al., 2012; Regulski et al., 2012).

Another interesting example is the first bifunctional PGH reported, produced by *Ped. acidilactici* ATCC 8042 that possess two identified lytic sites: N-acetylglucosaminidase and N-acetilmuramoyl-L-alanine amidase activities (Figure 3). These results could help in the design of new antibacterial agents of natural origin that can combat food-borne diseases and improve hygienic practices in the industrial sector (Carrillo et al., 2014; Serrano-Maldonado et al., 2018). Moreover, the search for new and natural antimicrobials includes the PGH produced by *Lb. sakei* active against various food-spoilage microorganisms. As shown in Figure 3, this PGH possess a lytic domain with N-acetyl-muramoyl-L-alanine amidase activity joined to a LysM region (small globular domains ranging in length from 44 to 65 amino acids that bind to various PG types) (Mesnage et al., 2014; López-Arvizu, García-Cano & Ponce-Alquicira, 2017). In similar studies from the twelve predicted PGH-encoding genes in the genome of *Lb. plantarum*, two PGHs were identified, the N-acetylglucosaminidase Acm2 and NpIC/P60 D,L- endopeptidase LytA. Both enzymes revealed a potential hydrolytic activities being the Acm2 the mayor autolysin produced by *Lb. plantarum* (Rolain et al., 2012). *Lb. plantarum* extracts with N-acetylglucosaminidase activity were capable to inhibit several microorganisms such as *Listeria innocua*, *Staphylococcus aureus*, *Weissella viridescens* and *Leuconostoc (Leuc.) mesenteroides* and where been applied to increase the shelf life of type Vienna sausage (García-Cano, 2013; Roa, 2017).

Clinical Applications of Peptidoglycan Hydrolases

It has been claimed that PGHs can help modulate the bacterial colonization of the gastrointestinal mucosa and the control of pathogenic bacteria that would be beneficial for human and animal health. The effectiveness of antibiotics against bacterial infections is decreasing due to the development of resistance in bacteria. Therefore, there is an increasing need for potential alternatives to the use of antibiotics. PGHs can be used as alternative antibacterial agents by its ability to hydrolyze the bacterial and fungi cell wall (Sharma et al., 2016). The medical applications of the recombinant lysostaphin are moving and some have entered into clinical trials (Nelson et al., 2012). The CWT domain of lysostaphin has also been considered as a promising source for alternative chemotherapy (Schmelcher et al., 2012; Osipovitch and Griswold 2014; Jagielska, Chojnacka, & Sabała, 2016) and has been redesigned to suppress its immunogenic potential (Blazanovic et al., 2015; Tossavainen et al., 2018).

As previously mentioned, lysostaphin is active against the cell wall of *S. aureus*, this microorganism has an annual incidence rate of infections from 20 to 50 cases/100,000 habitants, with 10 to 30% mortality especially for the presence of resistant strains in elderly

patients (van Hal et al., 2012). In addition to the health problem, productivity losses and the economic impact involved for the control of *S. aureus* represents a burden to society (van Hal et al., 2012; Lee et al., 2012; Kashani et al., 2017). Studies of peptidoglycan hydrolase like lysozyme and lysostaphin have been used successfully to control pathogenic bacteria resistant to antibiotics in animal models (Nakimbugwe et al., 2006; García-Cano et al., 2011).

Figure 3. Domain organization of (A) lysostaphin, B) N-acetylmuramoyl-L-alanine amidase produced by *Lb. sakei* and C) Bifunctional PGH produced by *Ped. acidilactici* ATCC 8042 (Modified from Sabala et al., 2014; García-Cano et al., 2015; López-Arvizu, García-Cano & Ponce-Alquicira, 2017).

The N-acetylmuramidases Lb GH25B and Lb GH25N produced by *Lb. buchneri* CD034 and NRRL B-30929 were identified as cell wall associated proteins with hydrolyzing activity. The stability of these proteins was determined through studies of thermal denaturation getting an assessment of the conditions that maintain biological activity with values of T_m around 49°C, reflecting the thermal stability of enzymes as needed for biotechnology and drug exploitation (Anzengruber et al., 2014). These values are consistent with those obtained for the glycanhydrolase Cpl-7 of *Strep. pneumoniae* bacteriophage Cpl17 recently studied as an antibacterial agent (Bustamante et al., 2012). N-acetylmuramidases from the *Lb.* genus contribute to the of cell wall hydrolases (CWHs), whose development as novel therapeutic proteins represent some advantages over conventional antibiotics, mainly due to their low probability for developing resistance (Parisien et al., 2008; Anzengruber et al., 2014). Surprisingly, LbGH25B and Lb GH25N do not contain any of the typical domains that generally exhibit the PGH; a multi-domain structure that includes a catalytic domain and multiple copies of a cell wall binding domain. The binding domains that are often found in this type of proteins are LysM, SH3, PG-binding, CW-binding, or Cpl-7 known to be present in the cell wall-associated proteins (Layec, Decaris and Leblond-Bourget 2008; Anzengruber et al., 2014).

It is interesting to mention that these domains give better anchoring properties to the cell wall of sensitive microorganisms and are also present in many PGHs; Alternatively, these structural domains, can be used for the identification of foreign peptides in the cell surface or for improvement of adhesion of host bacteria; as it has been used in the administration therapeutic proteins and vaccines to the mucosa (Berlec, Ravnikar & Strukelj, 2012). The oral administration of the traditional intravenous or intramuscular vaccine minimizes possible side effects while increasing the specificity of the mucosa chronic diseases and infections (Bermudez-Humarán et al., 2011; Wyszynska et al., 2015; Hynönen & Palva, 2013).

As already mentioned, activities of endopeptidases present in the S-layer of *Lactobacillus* also show potential for use as carriers of antigens in the design of live oral vaccines because of its adhesive and immunomodulatory properties, that can also be used in the mediation of

bacterial attachment to host cells (Prado-Acosta et al., 2008; Hynönen & Palva, 2013). Bacteria treated with this type of proteins, examined by electron microscopy reveal that they exert their lethal effects forming holes in the cell wall through the digestion of PG. The high internal pressure of bacterial cells (approximately 3 to 5 atmospheres) is controlled by the highly cross-linked cell wall. Any deterioration in the integrity of the wall will result in the extrusion of the cytoplasmic membrane and the final hypotonic lysis (Loessner et al., 2002).

Currently, with the exception of the polysporin and mupirocin, which are commonly used topically, no other antimicrobials may control pathogenic bacteria colonizing the mucous membranes. The selectivity for their inhibitory action against pathogenic bacteria without affecting the normal mucosa microbiota and the low likelihood of bacterial resistance, improves the potential of PGHs as a novel antimicrobials (34). Another example already mentioned is the application of the Lc-p75 (γ -D-glutamyl-L-lisil-endorpeptidase) produced by the probiotic *Lactobacillus casei* BL23, which presents an anti-inflammatory activity (Regulski et al., 2012).

CONCLUSION

Bacteriocins and peptidoglycan hydrolases are beneficial metabolites produced by lactic acid bacteria. LAB bacteriocins constitute a diverse and heterogeneous group of ribosomal antimicrobial peptides, varying in size, structure and specificity, active against closely related species. These peptides are considered food-grade because the GRAS or QPS status of most bacteriocinogenic strains, do not impart color or flavor and are easily degraded by the proteolytic enzymes, that makes them safe for human consumption, minimizing the opportunity of target strains to interact and develop resistance. Therefore, bacteriocins can be applied for food preservation, as well as, an alternative antibiotics in the clinical area, mainly due to their tolerance to high temperatures and their activity over a wide pH range against spoilage microorganisms and pathogens such *Bacillus*, *Clostridia*, *L. monocytogenes* and methicillin-resistant *S. aureus* and vancomycin-resistant *Enterococci* at concentrations lower than that for conventional antibiotics. Nevertheless, more research is needed in order to expand their inhibitory spectrum, stability and increase the recovery yields; where the bioengineering offers a possibility to enhance the inhibiting activity and spectra, as well as their heterologous expression in other hosts.

There is still few data in relation to PGHs produced by lactic acid bacteria in relation to their function and characterization. But PGHs offer a wide opportunity as alternative antimicrobials from GRAS microbial sources, with great prospects for new food applications as natural antimicrobial agents.

Chapter 298

BIOACTIVE PEPTIDES GENERATED BY LACTIC ACID BACTERIA

ABSTRACT

Numerous chronic diseases, including heart disease, stroke, cancer, and diabetes, have a significant influence on the health of people worldwide. Along with numerous preventive and therapeutic drug treatments, important advances have been achieved in the identification of bioactive peptides (BP) that may contribute to long-term health. Biopeptides with various biological activities have been found in several food matrices and by-products. Since microbial fermentation is one of the mechanisms for BP generation, lactic acid bacteria (LAB) arise as an ideal cell factory for their production. This chapter reviews the generation and biofunctional properties of various BP derived from meat and meat products, milk and dairy products, together with some other food substrates as beans and pseudo-cereals, which had been generated by several strains of LAB. Many apprehensions regarding their functionality and health-claims have been also considered.

INTRODUCTION

Bioactive peptides (BP) have been defined as specific protein fragments that have a positive impact on body functions and may influence health. They are encrypted within the sequence of the parent protein and can be released through hydrolysis by proteolytic enzymes.

* Corresponding Author's Email: mcastro@uncaus.edu.ar.

Hydrolysis can be performed either by endogenous enzymes in ripened foods, or by the combined action of endogenous and microbial enzymes when fermented, and/or by exogenous proteolytic enzymes (e.g., enzymes derived from microorganisms and plants) on isolated food proteins (Toldrá et al., 2016; Brown et al., 2017). Health benefits of BP are continuously being explored and discovered, hence, there are still controversies regarding their magnitude and significance. Lafarga & Hayes (2014) indicated that BP have antimicrobial, antioxidative, antithrombotic, antihypertensive, anticarcinogenic, satiety regulating and immunomodulatory activities and may affect the cardiovascular, immune, nervous and digestive systems. Peptides may also be effective in the treatment of mental health diseases, cancer, diabetes and obesity. Furthermore, many known BP are multifunctional and can present two or more health promoting activities which may or may not be related (Di Bernardini et al., 2011).

Among hydrolysis processes used to generate BP, microbial fermentation is the one addressed herein by lactic acid bacteria (LAB). The proteolytic system of LAB consists of a three steps breakdown process which comprises: I) a cell envelope-associated proteinase (CEP) - a key factor since it is responsible for the first breakdown of high molecular weight proteins, such as casein in milk-, II) specialized transport systems enabling the uptake of the resulting peptides, and III) numerous intracellular peptidases, which degrade peptides to amino acids. The activity of these biofunctional peptides relies on their inherent amino acid composition and sequence. The size of active sequences may vary from 2 to 30 amino acid residues, which can have one function or multifunctional health-beneficial properties. Once released, the BP may provide different functions that can be reproduced *in vitro* with biochemical assays or *in vivo* in cell or animal models and humans. Bioactive peptides that are being discovered are reported in several databases (BIOPEP, PEPBANK, ERP-Moscow and Brainpeps, among others), together with data about their chemical and structural characteristics, IC₅₀ (concentration necessary to inhibit 50% of enzymatic activity), protein of origin, etc. (Van Dorpe et al., 2012; Toldrá et al., 2018). The degree of proteolysis and the amount of generated BP depends on numerous variables including raw materials, type of enzyme activity, microbial population, and processing conditions. Up to the present time, the most studied biological functions have been antioxidant activity, and ACE-inhibitory activity, while antimicrobial activity, opioid activity, immunomodulation and antithrombotic activities have been lightly examined.

The production and commercialization of hydrolysates containing one or more BP have proved to be successful; however, many industrial obstacles limit the sales of nutraceutical or functional products. One of the main drawbacks is the regulation aspect and the application for a health claim authorization (Arroume et al., 2016). In this sense, foods fermented by LAB are of special interest to food manufacturers and consumers because of their additional probiotic health-promoting and therapeutic benefits.

Along with the advent of increasing analytical technology comes the discovery of 'functional foods' which -unsurprisingly- have been nurturing human beings since ancient times. Such is the case of a broad spectrum of food sources, i.e. animal, plant, microalgae and fungi, which have been delivering BP through microbial fermentation. Lactic acid bacteria comprise a widespread microbiota responsible for many of these fermentations. In the following sections, an overview of this topic is presented focusing primarily on the bioactivity displayed by the BP generated in each food substrate.

ANTIOXIDANT ACTIVITY

The mechanism of antioxidant activity of peptides is yet not sufficiently elucidated in the literature. Based on current knowledge, it is supposed that they may exert their antioxidant effect through the scavenging of free radicals and reactive oxygen species (ROS), inhibiting lipid peroxidation and chelating transition metal ions. Their action may be determined by factors such as position of the peptide in the protein structure, hydrophobicity, protein isolation method, degree of hydrolysis, type of enzymes used, concentration of peptide and amino acid configuration (Standik & Keska, 2015). The antioxidant activity of the peptides depends on the type of their component amino acids (Toldrá et al., 2018). As regards to amino acid types, aromatic amino acids such as *Tyr*, *His*, *Trp*, and *Phe* are prone to donate protons contributing to the radical-scavenging properties (Rajapakse et al., 2005). Besides, the hydrophobic amino acids have been described to be able to increase the presence of peptides at the water-lipid interface and then access to scavenge free radicals from the lipid phase (Ranathunga et al., 2006). Lastly, acidic amino acids utilize carbonyl and amino groups in the side chain which function as chelators of metal ions (Suetsuna et al., 2000).

In the last decade, several studies have evaluated the potential effect of LAB strains in the production of antioxidant peptides in different food matrices aiming at endorsing the health benefits associated with functional foods. Keska & Standik (2018) evaluated the stability of antiradical activity of protein extracts from LAB-inoculated dry-cured pork loins during long-term aging before and after simulated gastrointestinal digestion with pepsin and pancreatin. The microorganisms tested were *Lactobacillus* (*Lb.*) *rhamnosus* LOCK900, *Lb. acidophilus* BAUER L0938, and *Bifidobacterium* (*B.*) *animalis* ssp. *lactis* BB12. The highest antiradical effects were achieved for loins with *Lb. acidophilus* BAUER L0938 after 90 and 180 days of aging and *B. animalis* ssp. *lactis* BB12 in 270 days in the water soluble protein fraction. The highest biological activity was reached after 90 days of aging due to the hydrolytic degradation of proteins under the action of pepsin. During this period, *B. animalis* ssp. *lactis* BB12 showed higher values of biological activity. Mejri et al., (2017) evaluated the generation of antioxidant peptides in dry fermented camel sausages inoculated with different starters cultures: *Staphylococcus* (*S.*) *xylosus* and *Lb. plantarum*; *S. xylosus* and *Lb. pentosus*; *S. carnosus* and *Lb. sakei*. They observed a significant increase in the production of antioxidant peptides during camel sausage ripening for 28 days, particularly in the release of peptides of molecular weight above 3 kDa. The accumulation of antioxidant peptides achieved the highest antioxidant values at the end of ripening, measured by ABTS, DPPH, inhibition of hydroxyl radicals, and FRAP assays. This bacterial growth resulted in an increasing amount of peptides with molecular weights below 3 kDa. In general, antioxidant capacities in non-inoculated sausages were lower than the observed for inoculated sausages, especially for the sausage inoculated with *S. xylosus* and *Lb. plantarum*. In keeping with these results, Ayyash et al., (2019a) found that the smallest peptides (<3kDa) were the ones linked with the most potent antiradical activity; being these peptides mostly generated by *Lb. plantarum* KX881772 in camel meat dry sausages.

Regarding milk as a substrate, several authors reported antioxidant activity peptides generated by LAB. Aguilar-Toalá et al., (2017) described that the growth of *Lb. plantarum* strains in whole bovine milk led to the production of crude extracts rich in antioxidants. After the isolation of two fractions (<3 kDa and 3-10 kDa), these authors observed a strong

relationship among small peptides (<3 kDa) with antioxidant activity measured by DPPH and ABTS assays. Nevertheless, they found that peptides of molecular weight in the range 3-10 kDa also contributed to antioxidant potential of fermented whole bovine milk. Moreover, other studies support the use of different LAB, such as *Lb. helveticus* (Elfahri et al., 2016); *Lb. rhamnosus*, *Lb. paracasei*, and *Lb. casei* (Solieri et al., 2015), to induce the release of antioxidant peptides in milk. Mohanty et al., (2016) reported *Lb. delbrueckii* subsp. *bulgaricus* IFO13953 as a producer of an antioxidant peptide whose amino acid sequence was identified. Besides, antioxidant activities were reported from cow and camel milks fermented by specific strains of *Lb. plantarum*, *Lb. paraplantarum*, *Lb. kefir*, *Lb. gasseri*, and *Lb. paracasei* (Soleymanzadeh et al., 2016). Ayyash et al., (2017) also reported antioxidant activity in camel and cow milks fermented with *Lb. plantarum* and *Lb. reuteri*. El-Fattah et al., (2016) reported ACE inhibition and antioxidant activities after milk fermentation in 14 commercial dairy starters, which exhibited different degrees of proteolysis.

On wheat and other cereals, antioxidant peptides were described as the result of LAB activity (Coda et al., 2012). Generally, the high proline content of gluten alpha gliadins prevents hydrolysis by enzymes of the gastrointestinal tract, whereas LAB possess proline-specific peptidase systems. Alternatively, peptide degradation was achieved by the combined action of peptidase from different LAB strains simultaneously present in fermented food (Gerez et al., 2008). Ayyash et al., (2019b) investigated antioxidant activities on solid-state fermented (SSF) whole grain lupin, quinoa and wheat using *Lb. reuteri* KX881777 and *Lb. plantarum* KX881779. All quinoa fractions had an increase in DPPH after 24 h of fermentation. *Lb. reuteri* had the highest DPPH % in quinoa fraction compared with lupin and wheat fraction. Likewise, quinoa fermented by *Lb. reuteri* and *Lb. plantarum* had the greatest ABTS % compared with lupin and wheat fraction. The higher antioxidant activities in fermented quinoa fraction may be attributed to the nature of proteolytic products released and to other non-phenolic compounds with antioxidant activities. The antioxidant results in lupin fraction were in agreement with those reported by Fernández-Orozco et al., (2008) who run a similar fermentation with a strain of *Lb. sakei*. Besides, the fermentation of quinoa flour by *Lb. plantarum* (22 strains), *Lb. rossiae* (1 strain) and *Pediococcus* (*Ped.*) *pentosaceus* (3 strains) produced fermented quinoa flour extracts of high antioxidant activity (Rizzello et al., 2017). The authors observed that antioxidant activity was strain-dependent wherein *Lb. plantarum* strains displayed the highest capacity to breakdown quinoa proteins to antioxidant. The antioxidant activities in quinoa fermented for 24 h by *Lb. plantarum* was attributed to short chain peptides (<9.0 kDa).

ANTIHYPERTENSIVE ACTIVITY

The BP with antihypertensive activity - which mainly takes place through inhibition of the angiotensin I-converting enzyme (ACE) - has become of particular interest to the scientific community over the last few years. Within the regulation of blood pressure, ACE is a key enzyme that catalyzes the conversion of angiotensin I into angiotensin II, a potent vasoconstrictor, and inactivates bradykinin, a vasodilator (Ondetti & Cushman 1977). The higher the ACE activity, the higher the angiotensin II level, and the more likely that malignant hypertension (high blood pressure) develops. Hypertension is one of the risk

factors for coronary heart disease and stroke, being closely linked to the eating habits of industrialized countries (Lin et al., 2012).

Despite the fact that herein BP antioxidant and ACE inhibitory activities are presented separately, they usually appear together in the literature since the same sample fraction is implicated in both determinations. Hence, many of the studies aforementioned will sound familiar for the reader who had read the previous section.

The study of biopeptides generated in meat and meat products implies the acceptance of the presence of existent BP in the matrix before fermentation, hampering the determination of those BP generated exclusively by inoculated LAB. As an illustration, the increased ACE inhibition observed in fermented camel sausages suggested that the strain *Lb. plantarum* KX881772 improved the bioactivity of this meat product (Ayyash et al., 2019). The higher ACE inhibition in fermented camel sausages, compared with beef sausages, was attributed by the authors to a high degree of hydrolysis and/or the nature of camel meat peptides released during fermentation and storage. Mejri et al., (2017) also studied camel meat sausages whereas inoculated with different starter bacteria. They reported that the percentage of ACE inhibition was increased significantly in the whole extract and in all fractions during the 28 days of ripening. It could be noted that the highest ACE inhibition capacity was always observed for the fraction with peptides below 3 kDa. This assumption was in keeping with Escudero et al., (2013) and Mora et al., (2015) results, which stated that low molecular weight peptides (<3 kDa), contributing to the development of flavor in dry fermented meat products, could also exert antihypertensive activity. Moreover, ACE inhibition through ripening was significantly affected by the addition of a starter (*S. xylosus* and *Lb. plantarum*). These results were in accordance with those of Flores & Toldrá (2011) and Mora et al., (2015) who found that the action of microorganisms such as LAB could influence the last period of fermentation, contributing to the generation of small peptides and free amino acids.

Considering milk, the number of BP increases during the production of fermented milk products compared to raw milk and the composition of the peptide fraction changes due to the proteolytic action of the employed microorganisms (Hayes et al., 2007). Some studies investigated BP in traditional fermented milk products and identified, for instance, that the major ACE inhibitory peptide of Manchego cheese was attributed to the di-peptide FP, originated from hydrolysis of various casein fractions. A single peptide was responsible for the ACE inhibitory activity, which had an IC₅₀ value of 592 μ m (Gómez-Ruiz et al., 2002). Casein, as well as whey milk proteins, in particular α -lactalbumin and β -lactoglobulin, are a rich source of ACE-inhibitory peptides. These BP are naturally present in dairy products, generated during processing and ripening due to endogenous enzymes and microbial fermentation; besides, they are also released from milk protein sequences during gastrointestinal digestion by gastric and pancreatic enzymes (Seppo et al., 2003). The most significant examples of BP produced by *Lactobacillus* species in cheese are the antihypertensive tripeptides, Ile-Pro-Pro (IPP) and Val-Pro-Pro (VPP) -also called lactotripeptides-, generated from casein hydrolysis by different *Lb. helveticus* strains (Pihlanto, 2013). Moreover, sour milk fermented by *Lb. helveticus* contained ACE inhibitory tri-peptides (IPP and VPP) that lowered blood pressure in mild hypertensive subjects (Fekete et al., 2015). Jin et al., (2016) and Rutella et al., (2016) reported the presence of antihypertensive BP in yogurts and fermented milk products which are already being marketed (Hafeez et al., 2014; Raveschot et al., 2018). The magnitude of proteolysis would depend on the strain used. A good example of this situation is the work reported by Ahn et al.,

(2009) where whey fermented by *Lb. brevis* had a stronger ACE inhibitory ability than those fermented with *Lb. acidophilus*, *Lb. bifementans*, *Lb. casei*, *Lb. helveticus*, *Lb. paracasei*, *Lb. plantarum* and *Lb. reuteri*. Consequently, the functionality of protein hydrolysates may differ between cultures since microorganisms have different proteolytic systems. Even within the same species, different extent of hydrolysis, titratable acidity, free amino nitrogen and ACE inhibitory activities can be expected, as reported in skim milk fermented with 37 different *Lb. helveticus* strains (Chen et al., 2014).

In addition to the milk products already mentioned, kefir comprises another source of BP. Quirós et al., (2005) revealed two ACE inhibitory peptides in caprine kefir. Compared to some other fermented dairy products, kefir showed a higher rate of proteolysis and could, therefore, be a good source of physiologically active peptides (Ebner et al., 2015). Results from the latter study demonstrated that fermentation caused the additional release of peptides compared to unfermented milk. It could be concluded that the fermentation process improved the health promoting effects of milk that arose from the presence of bioactive peptides, namely 236 of the identified peptides were unique for kefir. Consequently, not only the concentration of bioactive peptides may increase during the fermentation process, but the bioactivity profile may also be completely different in kefir compared to milk. While the milk peptides are generated mainly by the action of endogenous proteinases like plasmin, cathepsins B, D and G, microbiological degradation plays a key role in fermented products. Two general specificity classes of proteinases are reported for lactococci, which are merely one part of the complex kefir microflora. As reported by Ebner et al., (2015), two of the identified bioactive peptides were of particular importance, i.e., casecidin 17 -a multifunctional peptide exerting antimicrobial, ACE-inhibitory, immunomodulating, antioxidant, and antithrombotic activities (Birkemo et al., 2009; Rojas-Ronquillo et al., 2012), and the peptide V- β -casomorphin-9 another multifunctional peptide showing ACE-inhibitory, antioxidant, and opioid activity (Eisele et al., 2013).

Soybean proteins have also been used as a source of ACE inhibitory proteins. According to Daliri et al., (2018) soy protein isolates consists of 90% protein; their components being 34% glycininand and 27% β -conglycinin. The many benefits of soybean proteins to reduce cholesterol levels (Hoie et al., 2007), reduce the risk of cardiovascular disease (Xiao, 2008), reduce the risk of breast cancer (Nagata et al., 2007), and lower blood pressure (Aluko, 2015) are well established and correlated with intensive studies. Vallabha & Tikku (2014) used a *Lb. casei* spp. *pseudopplantarum* strain to produce fermented soy protein concentrates. Their results showed a strong ACE inhibitory potency ($IC_{50} = 3.7$ mg/mL) of the fermented concentrate, while its isolated ACE inhibitory peptide LIVTQ displayed a higher potency ($IC_{50} = 0.087$ μ M). ACE inhibitory peptides (IFL and WL) isolated from tofu also displayed strong ACE inhibitory abilities (IC_{50} values of 44.8 and 29.9 μ M, respectively) indicating their potential to reduce high blood pressure (Kuba et al., 2003). Moreover, fermentation *Ped. pentosaceus* SDL1409 on soybean protein isolates for 48 h at 37°C generated a strong angiotensin I-converting enzyme inhibitory ability of $65.1 \pm 0.78\%$ ($IC_{50} = 0.123 \pm 0.02$ mg protein/mL). In this sense, Daliri et al., (2018) demonstrated that *Ped. pentosaceus* SDL 1409 could be useful for developing antihypertensive functional foods from soybean proteins.

EMERGING BIOACTIVITIES

In addition to both main health-promoting activities previously mentioned, several other bioactivities have been related to peptides generated by LAB fermentation. Hypocholesterolemic and antithrombotic peptides have been described to modulate the cardiovascular system whereas mineral binding and immunomodulatory peptides act in gastrointestinal and immune systems, respectively. Some groups of peptides are able to participate in multiple system reactions. Thus, opioid agonist and antagonists can act on nervous, gastrointestinal, and immune systems, whereas antimicrobial peptides can modulate gastrointestinal and immune systems (Lafarga & Hayes, 2014). The main problem of naturally generated peptides is the difficulty in controlling the hydrolysis conditions because many endogenous enzymes are acting at the same time and a wide profile of peptides showing different sizes and characteristics is generated (Mora et al., 2015). Despite the well documented evidence supporting these peptides bioactivities, trials were mainly conducted *in vitro*, giving scarce information about the availability and functionality of BP *in vivo*. For this reason, only few studies herein have been selected to illustrate the emerging bioactivities that had been investigated until the present time, taking into consideration that this scenario will evolve quickly, and that deeper comprehensive investigations would have to enrich this description in the near future.

The antithrombotic peptide YQEPVLGPVRGPFPIIV was generated by *Lb. casei* from bovine casein. This peptide not only presented antithrombotic activity but also inhibited ACE when tested *in vitro*. Besides, the peptide was able to maintain its bioactivity after enzymatic treatment with pepsin and trypsin (Rojas-Ronquillo et al., 2012). Very few meat-derived antithrombotic peptides have been described in the literature, being the few ones derived from the hydrolysis of papain, namely not from bacterial activity (Morimatsu et al., 1996; Shimizu et al., 2009).

Beta-caseins (β -CNs) harbor β -casomorphins (β -CMs) which are opioid peptides encrypted in an inactive form and can be released by enzymatic hydrolysis during fermentation and *in vivo* or *in vitro* gastrointestinal digestion (Asledottir et al., 2017; De Noni et al., 2015). Beta-CN fragments, β -CM5 (Tyr-Pro-Phe-Pro-Gly) and β -CM7 (Tyr-Pro-Phe-Pro-Gly-Pro-Ile) have strong opioid activity and are currently being extensively studied for their biological activity and their occurrence in a wide range of dairy products (Boutrou et al., 2013; De Noni et al., 2015; Nguyen et al., 2015). Nguyen et al., (2018) found that there were significant differences between the peptides generated by either *Streptococcus (Strep.) thermophilus* or *Lb. delbrueckii* ssp. *bulgaricus* fermenting UHT milk alone. They also determined that even the peptide profile generated by both strains as a mixed culture had a different peptide composition. These findings suggested that a new peptide was released by *Lb. delbrueckii* ssp. *bulgaricus* at the expense of an unknown enzyme derived from *Strep. thermophilus*.

Immunomodulating activity has been especially detected in peptides derived from milk and dairy products. These studies show that their length can be very different comprising from 2 to 64 amino acids, although those smaller than 3 KDa are the most abundant (Reyes-Díaz et al., 2016). Milk fermented by *Lb. helveticus* showed immunomodulating effect after administration to mice, whereas this bioactivity was not observed when mice were treated with milk fermented by a non-proteolytic variant of the same *Lb. helveticus* strain (Matar et

al., 2001). Additionally, the possible impact of milk fermented by *Lb. helveticus* on sleep efficiency in elderly subjects was demonstrated in a clinical study (Yamamura et al., 2009). A beneficial effect of fermented milk on bone metabolism was observed in animal or human clinical studies, probably because of the high calcium concentration and bioavailability in these products (Rizzoli & Biver, 2017). A previous work by Kim and coworkers (2009) showed a positive influence on bone metabolism in ovariectomized rats exerted by milk fermented with *Lb. casei* 393. Seemingly, Narva et al., (2004 a,b) observed improvements in bone metabolism of rats fed with milk fermented by *Lb. helveticus* strains, and even on calcium metabolism in postmenopausal women.

CONCLUSION

Despite the relatively inexpensive production cost of BP by LAB species compared to the use of purified enzymes, there are still some challenges for further industrial exploitation of these bacteria; mainly the poor characterization of CEPs from different species and the low yields of peptide production by fermentation. Future and deeper studies employing LAB as BP factories have the potential to generate new peptide sequences and, therefore, new biopeptides with specific biological properties. According to Raveschot et al., (2018), metabolic engineering of the proteolytic system of LAB could overcome these challenges.

A few functional, peptide-based, products have already been launched on the market. Most of these were derived from milk, plant and marine sources. This trend is likely to continue as knowledge about the bioactivities and properties of peptides increases (Lafarga & Hayes, 2014). However, a word of caution is to be addressed on BP as a whole, since there are yet no general rules for determining the best hydrolysate with the most important activity. Each raw material, each enzyme and each hydrolysis conditions will give different final peptides. Hence, health claims and beneficial effects for the general population must be considered as ‘potential advantages’ more than ‘effective health promoters.’

ABSTRACT

Lactic acid bacteria (LAB) are known to be present in diverse origins which are rich in nutrients and energy sources, for instance, milk, meat, plants and gastrointestinal tract of humans and animals. LAB that have extensively been found to belong to the genera *Lactobacillus* (Lb), *Streptococcus* (Strep), *Enterococcus* (Ec), *Pediococcus* (Ped), *Lactococcus* (Lc), *Leuconostoc* (Leuc), *Aerococcus* (A), *Oenococcus* (O), *Carnobacterium* (Cb), *Vagococcus* (V), *Tetragenococcus* (T), *Weissella* (W) and *Fructobacillus* (F) (a genus of fructophilic lactic acid bacteria). They can produce lactic acid as the primary metabolic end product via carbohydrate metabolisms. Therefore, various fermented foods are developed by the action of these bacteria. Antimicrobial compounds secreted by LAB have long been recognized to prolong the shelf-life and improve the safety of foods. LAB produce a variety of compounds, including lactic acid, acetic acid, hydrogen peroxide (H₂O₂), ethanol, formic acid, fatty acids, diacetyl, acetaldehyde, acetoin, reuterin, reutericyclin, bacteriocins, bacteriocin-like compounds and other low molecular mass compounds which exhibit the antimicrobial activity against spoilage and pathogenic microorganisms and germination of spore as well. LAB cultures are marketed today as protective cultures against common food spoilage bacteria and pathogens. Consequently, the application of such cultures may lead to improvements in food quality and sensory attributes by controlling spoilage microbiota. The use of antimicrobials from LAB as food preservatives has become a popular practice. Moreover, the addition of LAB as probiotics into food and medical products has also been reported.

INTRODUCTION

The interest in naturally- or bio-preservation has been increasing during recent years. For this reason, many researchers have been paying attention on antagonistic microorganisms and their antimicrobial metabolites for application in the food industry (Reis et al., 2012). Among the microorganisms, lactic acid bacteria (LAB) are fascinating since ancient time; many kinds of food are fermented naturally by autochthonous LAB, which form the desirable characteristics of the products. The action of these bacteria can improve texture, flavor, odor and taste of foods. These phenomena are responsible from the generation of numerous metabolites such as lactic acid, acetic acid, ethanol, diacetyl, acetone, exopolysaccharide, specific proteases and bacteriocin by fermentation (Porto et al., 2017). The reduction of pH and conversion of sugars to organic acids are the primary preserving actions that these bacteria provide to fermented food. Therefore, shelf-life of foods is extended and the safety for consumption is ensured. In addition to organic acids, other antimicrobials produced by LAB; H₂O₂, ethanol, formic acid, fatty acids, diacetyl, acetaldehyde, acetoin, reuterin, reutericyclin, bacteriocins, bacteriocin-like substances (BLIS) also exhibit antagonistic activity against undesirable microorganisms (Šušković et al., 2010).

In regard to antagonistic property, LAB are used as protective cultures and preservatives in food-based products because of their bioactive compound production. Furthermore, they are also developed as the pure and mixed culture for the alleviation of human suffering from the pathogenic infection. In this chapter, we focus on the diversity of LAB distributed in natural materials, their antimicrobials, antimicrobial spectrum and application of LAB in food products and clinical alleviation.

LAB AND HABITATS

LAB comprise a clade of Gram-positive bacteria integrated by a cluster of morphological, metabolic, and physiological characteristics (Axelsson, 2004). They are catalase-negative, acid tolerant, non-sporulating, non-respiring rods or cocci that produce lactic acid as the major metabolic end-product of carbohydrates fermentation (Salminen et al., 1996; Klaenhammer & de Vos, 2011). They have less than 55% mol G+C content in their DNA (Stiles & Holzapfel, 1997). LAB consisted of several genera including *Lactobacillus* (Lb), *Streptococcus* (Strep), *Enterococcus* (Ec), *Pediococcus* (Ped), *Lactococcus* (Lc), *Leuconostoc* (Leuc), *Aerococcus* (A), *Oenococcus* (O), *Carnobacterium* (Cb), *Vagococcus* (V), *Tetragenococcus* (T), *Weissella* (W) and *Fructobacillus* (F) (Axelsson, 2004). Among these genera, *Lactobacillus* is the largest genus (Parte, 2018). LAB can be divided into two groups based on their glucose metabolisms including homofermentative LAB which converted glucose almost quantitatively to lactic acid (more than 85%) through Embden-Meyerhof-Parnas or glycolysis pathway and heterofermentative LAB which fermented glucose to lactic acid (50%), ethanol/acetic acid, and CO₂ through the phosphoketolase pathway (Reddy et al., 2008).

LAB require numerous essential nutrition for their growth; hence, distribution of LAB is associated with the sources containing the high concentration of carbohydrates, amino acid, vitamins, purines and pyrimidines (Saguir et al., 2007). Consequently, LAB are typically

detected in a large number of natural sources that are rich-nutrients such as dairy, meat, cereal, plants, and their fermentative products, and functioned as natural inhabitants gastro-intestinal (GI) tract of human and animals. These bacteria produce many metabolic products especially, lactic acid that provide a unique characteristic of each fermented product. *Lactobacillus* seems to be the most widespread LAB which distributed in these environments. *Lb. plantarum*, *Lb. reuteri*, *Lb. delbrueckii* subsp. *lactis*, *Lb. delbrueckii* subsp. *bulgaricus*, *Lb. paracasei*, *Lb. curvatus*, *Lb. rhamnosus*, *Lb. fructivorans*, *Lb. parabuchneri*, *Lb. brevis*, *Lb. animalis*, *Lb. curvatus*, *Lb. fermentum*, *Lb. helveticus*, *Lb. kefir*, *Ec. faecium*, *Ec. faecalis*, *Ec. devriesei*, *Ec. durans*, *Ec. saccharominimus*, *Lc. lactis*, *Lc. garvieae*, *Leuc. pseudomesenteroides*, *Leuc. mesenteroides*, *Leuc. lactis*, *Leuc. citreum*, *W. viridescens*, *Strep. thermophilus* and *Strep. bovis* are isolated from dairy-based products including camel milk, goat milk, cow milk, Greek traditional yoghurt, fermented milk, Maroilles (French cheese) and Romanian dairy products (Zamfir et al., 2006; Tormo et al., 2015; Abushelaibi et al., 2017; Georgalaki et al., 2017; Nacef et al., 2017). Various species of LAB including *Lb. sakei*, *Lb. casei*, *Lb. plantarum*, *Lb. paraplantarum*, *Lb. paracasei*, *Lb. johnsonii*, *Lb. brevis*, *Lb. curvatus*, *Lb. fermentum*, *Lb. graminis*, *Lb. carnosus*, *Ped. pentosaceus*, *Ped. acidilactici*, *Ec. faecalis*, *Ec. faecium*, *W. cibaria*, *W. confusa*, *W. halotolerans*, *Leuc. inhae*, *Leuc. mesenteroides*, *Leuc. carnosum*, *Leuc. citreum*, *Lc. lactis* and *Carnobacterium* spp. are existed in meat-originated products such as Ciauscolo salami, dry-salted cod and albacore muscle, Harbin dry sausages, Uzicka sausages, Pastırma (traditional meat product in Turkey) and Lukanka (traditional Bulgarian fermented meat product) (Federici et al., 2014; Gómez-Sala et al., 2015; Moracanin et al., 2015; Han et al., 2017; Öz et al., 2017; Todorov et al., 2017). *Lb. plantarum*, *Ped. pentosaceus*, *Ped. acidilactici*, *Lb. brevis*, *Lb. coryniformis*, *Lb. paracasei*, *Lb. fermentum*, *Lb. rhamnosus*, *Lb. sakei*, *Lb. sanfranciscensis*, *Lb. crustorum*, *Lb. paralimentarius*, *Lb. rossiae*, *Lb. mindensis*, *Lb. helveticus*, *Lc. lactis*, *Lc. garvieae*, *Ec. casseliflavus*, *Ec. faecium*, *Ec. faecalis*, *Ec. mundtii*, *Ec. hirae*, *Ec. gallinarum*, *Ec. hermanni*, *Leuc. citreum*, *Leuc. mesenteroides* and *W. confusa* are involved in cereal-based products i.e., wheat, brewer's grains, quinoa grains and sourdough, Nigerian fermented cereal-based foods and Chinese traditional sourdough (Asurmendi et al., 2015; Carrizo et al., 2016; Liu et al., 2016; Alfonzo et al., 2017; Adesulu-Dahunsi et al., 2018). *Lb. plantarum*, *Lb. brevis*, *Lb. paracasei*, *Lb. fermentum*, *Lb. casei*, *Lc. lactis*, *Lc. mesenteroides*, *Ped. pentosaceus*, *Lb. kunkeei*, *Lb. florum*, *F. pseudoficulneus*, *F. fructosus*, *Ec. durans*, are found in plant-derived product for instance; fruit (pulp and byproduct of *Malphigia glabra* L. and *Mangifera indica* L., and *Annona muricata* L.), fresh flowers and fruit peels, Kahudi (traditional rapeseed fermented food) (Endo et al., 2009; Endo et al. 2010; Goswami et al., 2017; Da Costa et al., 2018). Noteworthy, the species belonged to genus *Fructobacillus* are found only in fructose-rich origins such as flower and fruit. The indigenous species to human, *Lb. paracasei*, *Lb. casei*, *Lb. gasseri*, *Lb. fermentum*, *Lb. rhamnosus*, *Lb. oris*, *Lb. vaginalis*, *Lb. ruminis*, *Lb. plantarum*, *Lb. pentosus*, *Lb. salivarius*, *Lb. saerimneri*, *Lb. johnsonii*, *Lb. reuteri* and *W. confusa* are presented in GI tract of human (Ladda et al., 2015; Noguchi et al., 2012; Rubio et al., 2014; Taweechotipatr et al., 2009; Spinler et al., 2008). Intestine samples of summer adult worker bees (*Apis mellifera* L.) from different hives are used for LAB isolation. *Lb. acidophilus*, *Lb. crispatus*, *Lb. johnsonii*, *Ec. faecium*, *Lactobacillus* spp. and *Enterococcus* spp. are found in the samples (Audisio et al., 2011). In marine animals, *Leuc. mesenteroides*, *Leuc. lactis*, *Lb. pentosus*, *W. cibaria*, *W. confusa*, *Lb. plantarum*, *Ped. pentosaceus* are isolated from fish gut, marine fish, shellfish and shrimp (Hongpattarakere et

al., 2012; Gurovic et al. 2014). *Lb. johnsonii*, *Lb. mucosae*, *Lb. murinus*, *Lb. salivarius*, *Lb. amylovorus*, *Lb. fermentum*, *Lb. perolens*, *Lb. reuteri*, *Lb. johnsonii*, *Lb. acidophilus*, *Lb. animalis*, *Lb. casei*, *Lb. farciminis*, *W. paramesenteroides*, *W. cibaria*, *W. hellenica* and *Ec. faecium* are existed in GI tract of calves (Maldonado et al., 2012; Sandes et al., 2017). *Ec. durans*, *Ec. faecium*, *Ec. hirae*, *Ped. acidilactici*, *Ped. pentosus*, *W. paramesenteroides*, *Lb. acidophilus*, *Lb. amylovorus*, *Lb. buchneri*, *Lb. mucosae* and *Lb. plantarum* are isolated from cattle faeces (Maldonado et al., 2018).

ANTIMICROBIAL PRODUCTS

LAB can produce several active metabolites against other microorganisms such as organic acids (lactic, acetic, formic, propionic and butyric acids), that intensify their action by reducing the pH of the media, and other substances, such as ethanol, fatty acids, acetoin, hydrogen peroxide, diacetyl, antifungal compounds (propionate, phenyl-lactate, hydroxyphenyl-lactate, cyclic dipeptides and 3-hydroxy fatty acids), bacteriocins (nisin, pediocin, lacticin, enterocin and others) and bacteriocin-like inhibitory substances (BLIS), reuterin and reutericyclin (Reis et al., 2012). These LAB metabolic products have a positive effect on food taste, smell, color, and texture, but they may also have the beneficial side effects of extending shelf-life and inhibiting the growth of pathogenic organisms (O'Bryan et al., 2015). Antimicrobial substances produced by LAB can be divided into two groups (Šušković et al., 2010) including:

Table 1. Low molecular mass antimicrobial metabolites of lactic acid bacteria (modified from Šušković et al., 2010)

Compound	Producers	Indicator strains
Lactic acid	All LAB	Yeasts, Gram-positive bacteria, Gram-negative bacteria
Acetic acid	Heterofermentative LAB	Yeasts, Gram-positive bacteria, Gram-negative bacteria
Diacetyl, acetaldehyde, acetoin	Variety of genera of LAB including: <i>Lactococcus</i> , <i>Leuconostoc</i> , <i>Lactobacillus</i> and <i>Pediococcus</i>	Yeasts, Gram-positive bacteria, Gram-negative bacteria
Hydrogen peroxide	All LAB	Yeasts, Gram-positive bacteria, Gram-negative bacteria
Carbon dioxide	Heterofermentative LAB	Most of microorganisms
Reuterin	<i>Lb. reuteri</i>	Fungi, protozoa, Gram-positive and Gram-negative bacteria
Reutericyclin	<i>Lb. reuteri</i>	Gram-positive bacteria
Cyclic dipeptides	<i>Lb. plantarum</i> , <i>Lb. pentosus</i>	Fungi
3-Phenyllactic acid, 4-hydroxyphenyllactic acid	<i>Lb. plantarum</i> , <i>Lb. alimentarius</i> , <i>Lb. rhamnosus</i> , <i>Lb. sanfranciscensis</i> , <i>Lb. hilgardii</i> , <i>Leuc. citreum</i> , <i>Lb. brevis</i> , <i>Lb. acidophilus</i> , <i>Leuc. mesenteroides</i>	Fungi
3-Hydroxy fatty acids	<i>Lb. plantarum</i>	Fungi
Benzoic acid, methylhydantoin, mevalonolactone	<i>Lb. plantarum</i>	Fungi, Gram-negative bacteria

1) Low molecular mass substances (< 1,000 Da): Organic acids, hydrogen peroxide, diacetyl, acetaldehyde and acetoin, carbon dioxide, reuterin, reutericyclin, cyclic dipeptides, phenyllactic acid, 4-hydroxyphenyllactic acid and 3-hydroxy fatty acids (Table 1)

2) High molecular mass substances (> 1,000 Da): Bacteriocins are ribosomally-synthesized peptides or proteins with the anti-microbial activity that are produced by different groups of bacteria including many members of LAB (Gálvez et al., 2007.) Bacteriocins released from LAB are generally recognized as safe substances (GRAS); they have attracted interest to use extensively as food preservatives. Since nisin A was recognized in 1928, diverse bacteriocins have been identified from LAB (Zendo and Sonomoto, 2011). Interfering of the cell wall and or the membrane of target organisms, either by inhibiting cell wall biosynthesis or causing pore formation, consequently resulting in death, are the proposed anti-microbial mechanism of bacteriocins (O'Sullivan et al., 2002). Bacteriocins are classified into 4 groups based on their structures and characteristics (Table 2.).

Table 2. Suggested classification of bacteriocins from LAB (modified from Cotter et al., 2005; Šušković et al., 2010)

Classification	Major characteristics	Examples
Class I lantibiotics/lanthionine-containing bacteriocins subdivided into: Type A lantibiotics Type B lantibiotics	Small (< 5 kDa) membrane-active peptides containing unusual amino acids; – elongated peptides with a net positive charge – smaller globular peptide with negative or no net charge	Type A: Nisin, lactacin 481, lactacin S Type B: Mersacidin
Class II non-lanthionine-containing bacteriocins Subdivided into: Subclass IIa Subclass IIb Subclass IIc	Heterogeneous class of small (< 10 kDa) heat-stable post-translation unmodified non-lantibiotics IIa: pediocin-like IIb: two-peptide IIc: with wide range of effects on membrane permeability and cell wall formation	IIa: Pediocin PA1, sakacin A, sakacin P, leucocin A, curvacin A IIb: Lactococcin G, lactococcin M, lactacin F, plantaricin A IIc: Acidocin B, enterocin P, enterocin B, reuterin 6
Class III Bacteriolysins	Large (> 30 kDa) heat-labile antimicrobial proteins, complex proteins with domain-type structure that function through the lyses of sensitive cell by catalyzing cell wall hydrolysis	Lysostaphin, enterolysin A, helveticin J, helveticin V-1829
Class IV	Complex bacteriocins carrying lipid or carbohydrate moieties	Plantaricin S, leuconocin S, lactacin 27, pediocin SJ1

Bactericidal Activity

Gram-Negative Bacteria

Helicobacter pylori

Helicobacter (H) pylori was successfully cultivated by Warren and Marshall in 1983 who first described that this bacterium is associated with chronic gastritis and peptic ulcer (Warren

& Marshall, 1983). *H. pylori* commonly colonized on the mucous layer of the gastric epithelium of the human stomach. Hence, it has been isolated from materials of gastric sites of diverse populations throughout the world (Owen, 1995). Over the past two decades, increased attention had been paid on *H. pylori* since it plays an important role in the pathogenesis of chronic gastritis and peptic ulcer diseases. Both epidemiological and clinical evidence has indicated that *H. pylori* is associated with an increased risk of gastric carcinoma (Heavey & Rowland, 2004). The International Agency for Research into Cancer (IARC) and the World Health Organization (WHO) have classified this bacterium into Class I (definite) biological carcinogen in humans (Park et al., 2004). Nowadays, *H. pylori* infection remains a commonly spread disease with definite morbidity and mortality (Zullo et al., 2012). Moreover, the prevalence of infection in the developing countries was higher (greater than 80%) than the developed ones (less than 40%) (Vale & Vitor, 2010).

European guidelines suggested the standard triple therapies including a proton pump inhibitor (PPI), clarithromycin (500 mg) plus amoxicillin (1 g) or metronidazole/tinidazole (500 mg), all given twice daily for 7–14 days for *H. pylori* eradication (Zullo et al., 2012). Unfortunately, the decrease in the efficacy of this regimen occurred throughout the world during the last decade. Consequently, the sequential therapy 10-days therapy (was proposed to get better results than triple therapies. This novel regimen consisted of a PPI plus amoxicillin 1 g (both twice daily) given for the first five days followed by a triple therapy including a PPI, clarithromycin 500 mg, and tinidazole (all drugs were given twice daily) for the remaining five days. However, antibiotic-based treatment for *H. pylori* infection had a higher effect on the composition of intestinal microbiota (Myllyluoma et al., 2007). Besides, antibiotic-based therapy would not be cost-effective, causes side effects and in particular, encourages the spread antibiotic resistance (Michetti, 2001). Therefore, an increased interest of many researchers had been paid on LAB since some strains of these bacteria had exhibited antagonistic activity against *H. pylori*. Organic acids especially, lactic acid produced by LAB has well known to exhibit antibacterial activity against *H. pylori* which are related to pH value in the medium. Lactic acid produced by *Lb. acidophilus* suppresses the growth of all seven strains of *H. pylori* *in vitro* (Bhatia et al., 1989). Extracellular lactic acid secreted by *Lb. acidophilus* and *Lb. rhamnosus* inhibited the growth of *H. pylori* (Midolo et al., 1995). The spent culture supernatant (SCS) of the *Lb. acidophilus* strain LB (LB-SCS) dramatically decreased the viability of *H. pylori* *in vitro* independent of pH and lactic acid levels (Coconnier et al., 1998). LB activity was strain-dependent and better at low pH. *Lb. paraplantarum* KNUC25 isolated from over-fermented kimchi, is effective in inhibiting the growth of *H. pylori*, which is related to pH and the adherence of *cagA*-positive *H. pylori* to gastric cells (Ki et al., 2010). *Lb. acidophilus* LY5 produced lactic and acetic acid that reduced urease activity and the viability of both *H. pylori* BCRC 17021 and CMU83 (Lin et al., 2011). The investigation of Zheng et al. (2016) reported that *Lb. pentosus* strain LPS16 had the broad-spectrum antibacterial activity against multidrug-resistant *H. pylori* strains, suggesting that it can be used to prevent *H. pylori* infection. *Lb. fermentum* UCO-979C significantly inhibited *H. pylori*-induced IL-8 production in AGS cells and reduced the viability of *H. pylori* (García et al., 2017). The strains of *Lb. delbrueckii* subsp. *bulgaricus* inhibited many *H. pylori* strains, including antibiotic resistant strains by secreting lactic acid, bacteriocins-like substances or other bioactive substances (Boyanova et al., 2009). In addition to lactic acid and low pH, viable and nonviable *W. confusa* strain PL9001 inhibited the binding of *H. pylori* ATCC 43504 to human gastric-cell line MKN-45 cells by more than

90%. The spent culture supernatant of PL9001 rapidly decreased the viability of *H. pylori* and ruptured the cell walls by the action of bacteriocins (Nam et al., 2002). Kim et al. (2003) reported that the bacteriocins; nisin A, lacticin A164, lacticin BH5, lacticin JW3 lacticin NK24, pediocin PO2, and leucocin K produced from *Lc. lactis* subsp. *lactis* ATCC 11454, *Lc. lactis* subsp. *lactis* A164, *Lc. lactis* BH5, *Lc. lactis* JW3, *Lc. lactis* NK24, *Ped. acidilactici* PO2, and *Leuconostoc* sp. LAB145-3A, respectively, showed the anti-*H. pylori* activity. MICs of these bacteriocins were ranged from 0.39–25, 0.097–12.5, 0.097–12.5, 0.195–25, 0.097–25, 6.25–50 and 25 mg/L, respectively, that varied among the *H. pylori* strains tested, of which strain ATCC 43504 was the most tolerant. The inhibitory activity of *Ec. faecium* TM39 against *H. pylori* could result from the inhibition on *H. pylori* urease activity and the secreted bacteriocin-like substances (Tsai et al., 2004). *Lb. delbrueckii* subsp. *bulgaricus* BB18 isolated from authentic Bulgarian dairy products produced a novel bacteriocin (bulgaricin BB18) which contained the antagonistic activity against four tested strains of *H. pylori* (Simova et al., 2009). The cell-free culture supernatants obtained from *Lb. brevis* BK11, *Lb. acidophilus* BK13, *Ped. pentosaceus* BK34, *Lb. paracasei* BK57, and *Lc. lactis* BK65 strains producing very high levels of lactic acid dramatically decreased the viability of *H. pylori*. In addition, the bactericidal activity of *Lb. plantarum* BK10, *Lb. brevis* BK11, *Lb. acidophilus* BK13, *Lb. paracasei* BK57, and *Ec. faecalis* BK61 strains was significantly correlated with their bacteriocin production (Lim, 2014). Purified bacteriocin BK11 and BK61 (MW 6.5 and 4.5 kDa) produced from *Lb. brevis* BK11 and *Ec. faecalis* BK61, exhibited anti-*H. pylori* activity and lowered the urease activity of *H. pylori* (Lim, 2015).

Other Gram-Negative Bacteria

Bacteriocins produced by LAB generally possess antibacterial activity against Gram-positive foodborne pathogens (Zendo & Sonomoto, 2011). In recent years, many bacteriocins active against Gram-negative bacteria have been identified proving their efficacy in foods and treating infections (Ghodhbane et al., 2015). Therefore, the limitation of bacteriocins has been improved. There are some reports that demonstrated that bacteriocins have the ability to inhibit Gram-negative bacteria. In addition to anti-*H. pylori* activity, bulgaricin BB18 has an effect on the growth of other Gram-negative pathogens such as *Escherichia* (*E*) *coli* WF and *Salmonella* (*S*) *Typhimurium* FVK781 as well (Simova et al., 2009). Bacteriocin 7293A and B from *W. hellenica* BCC 7293 have broad antimicrobial spectra against many strains of tested Gram-positive bacteria and exceptionally inhibited several important Gram-negative food-borne pathogens such as *Pseudomonas aeruginosa*, *Aeromonas hydrophila*, *S. Typhimurium* and *E. coli* (Woraprayote et al., 2015). Strains of *Lc. lactis* isolated from tropical rainforest wild-type fruits produce antimicrobial substances which suppress the growth of 3 strains of *E. coli*, *S. enterica* subsp. *enterica*, *S. enterica* subsp. *Abaetetuba*, *Salmonella* sp., *Enterobacter* sp. and *Shigella sonnei* and *Shigella* sp. (Tenea et al., 2018). Active compounds in CFS from *Ec. faecalis* KT11 show antimicrobial activity against significant Gram-negative bacteria including *Klebsiella pneumoniae*, *Serratia marcescens*, *Enterobacter aerogenes*, *Pseudomonas aeruginosa* and *Kocuria rhizophila* (reclassified name of *Micrococcus luteus*) (Abanoz & Kunduhoglu, 2018).

Gram-Positive Bacteria

Listeria monocytogenes

Listeria (L) monocytogenes causes listeriosis, a rare foodborne disease with a mortality rate of 20%–30%. The elderly and immunocompromised hosts are particularly susceptible to listeriosis. *L. monocytogenes* is ubiquitous and can contaminate food-processing environments, posing a threat to the food chain. This is particularly important for ready-to-eat foods as there is no heat treatment or other antimicrobial steps between production and consumption. Thus, occurrence and control of *L. monocytogenes* are essential for industry and public health. Advances in whole-genome sequence technology are facilitating the investigation of disease outbreaks, linking sporadic cases to outbreaks, and linking outbreaks internationally. Novel control methods, such as bacteriophage and bacteriocins, can contribute to a reduction in the occurrence of *L. monocytogenes* in the food-processing environment, thereby reducing the risk of food contamination and contributing to a reduction of this public health issues (Jordan & McAuliffe, 2018).

Tomé et al. (2006) reported that lactic acid, hydrogen peroxides (H_2O_2) and bacteriocin produced by strains of *Lb. plantarum*, *Lb. brevis* and *Lc. lactis* showed inhibitory activity against *L. monocytogenes* isolated from cold smoked salmon. Two strains of *Ped. pentosaceus* isolated from Alheira, a traditional Portuguese fermented sausage demonstrated anti-*Listeria* activity of a proteinaceous nature (Albano et al., 2007). *Ec. faecium* MMZ17 isolated from Gueddid, a traditionally Tunisian fermented meat, produced enterocin MMZ17 which exhibited anti-*Listeria* activity. Enterocin MMZ17 can be classified as a small, heat-stable anti-*Listeria*-active peptide, presumably belonging to class IIa bacteriocins (Belgacem et al., 2008). Two bacteriocins similar to pediocin PA-1 and enterocin B secreted by *Ec. faecium* ALP7 and *Ped. pentosaceus* ALP57 (isolated from non-fermented seafood), reduced the growth of *L. monocytogenes* (Pinto et al., 2009). *Ped. pentosaceus* BCC 3772 isolated from Nham (a Thai fermented pork sausage), produced anti-*Listeria* activity during the early logarithmic growth phase with the maximum production of 520,000 AU/mL detected at 12 h of growth. The anti-*Listeria* substance was found to be a class IIa bacteriocin, subsequently identified as pediocin PA-1/AcH (Kingcha et al., 2012). Kimchi-derived *Ped. pentosaceus* showed an anti-*L. monocytogenes* activity. The active compound was identified the active moiety as a LysM domain in a 23-kDa protein that could potentially be a peptidoglycan hydrolase enzyme. This protein was stable over a wide pH range (pH 4–8) and heat treatment (80–100°C for 20 min) (Jang et al., 2014). *W. hellenica* BCC 7239, isolated from Thai fermented pork sausage called Nham, produced two putatively novel bacteriocins, 7293A and 7293B with the molecular mass 6249.302 and 6489.716 Da, respectively. Antimicrobial activity of both peptides was not inactivated by organic solvents (ethanol, isopropanol, acetone, acetonitrile) and surfactants (Tween 20, Tween 80 and Triton X-100). Both novel bacteriocins hold promise for applications in the prevention or treatment of pathogenic infections as food and feed additives to replace antibiotics for enhancing the productivity and sustainability of food production (Woraprayote et al., 2015). A bacteriocin with antagonistic activity against *L. monocytogenes* was produced by a strain of *Lc. lactis* (L3A21M1) which isolated from an Azorean cheese. This bacteriocin with a molecular mass of 2900.23 Da, similar to that of lacticin 481, was heat stable (100°C for 30 and 60 min), active across a wide pH range (2.0–12.0) that is useful for application in the fermentation process (Ribeiro et al.

2016). The two bacteriocins produced by *Ec. durans* 152 were characterized and identified as Dur 152A (an enterocin L50A derivative with two amino acid substitutions of I/M) and enterocin L50B. At 400 AU/mL, the bacteriocins prevented growth of *Listeria* in deli ham for at least 10 weeks at 8°C and at least 30 days at 15°C. For comparison, 500 ppm Nisin controlled *Listeria* growth for up to 6 weeks at 8°C and up to 18 days at 15°C (Du et al., 2017). Plantaricin LPL-1, produced by *Lb. plantarum* LPL-1, was a novel class IIa bacteriocin with bactericidal activity against *L. monocytogenes* 54002. The minimal inhibitory concentration (MIC) was confirmed as 16 µg/mL, and the time-kill kinetics showed that plantaricin LPL-1 significantly decrease the viable cell numbers of *L. monocytogenes* 54002 in a time-dependent and dose-dependent manner (Wang et al., 2019).

Other Gram-Positive Bacteria

Various organic acids, including acetic acid, lactic acid, citric acid, and malic acid have been shown to possess antibacterial effects and therefore are used as antibacterial additives. Organic acids released by *Ped. pentosaceus* strain T1 exert inhibiting effects against the significant pathogenic bacteria; *L. grayi*, *L. ivanovii* subsp. *ivanovii*, *L. innocua*, *L. seeligeri*, *Staphylococcus* (*St*) *aureus* subsp. *aureus*, *St. epidermidis*, *St. saprophyticus* subsp. *saprophyticus* and *Bacillus* (*B*) *cereus* (Jang et al., 2014). Bacteriocins produced by LAB have been widely known to inhibit their related species especially to Gram-positive bacteria (Zendo & Sonomoto, 2011). Several studies have reported that bacteriocins released by LAB had an interesting feature to decrease the number of Gram-positive pathogenic bacteria in many foods and clinical trials. Bacteriocin-containing CFS collected from *Ec. faecium* strains exhibited the suppression against *L. innocua*, *L. ivanovii* and strains of LAB such as *Lc. lactis* subsp. *cremoris*, *Lb. casei*, *Lb. curvatus*, *Lb. delbrueckii*, *Ec. faecalis*, *Ec. faecium* and *Ped. acidilactici* (Belgacem et al., 2008). The study of Woraprayote et al. (2015) indicated that many strains of Gram-positive bacteria (*B. circulans*, *B. coagulans*, *B. subtilis*, *Ec. faecalis*, *Ec. faecium*, *Lb. sakei* subsp. *sakei*, *Lc. lactis* subsp. *lactis*, *Leuc. mesenteroides* subsp. *mesenteroides*, *L. innocua*, *Ped. pentosaceus*, *St. aureus*, *St. xylosus*, *W. confusa*, *W. cibaria*, *W. paramesenteroides*, *W. hellenica*) are inhibited by the action of bacteriocin 7293A and 7293B secreted by *W. hellenica* BCC 7923. Methicillin-resistant *St. aureus* (MRSA) is a multidrug-resistant micro-organism and the important nosocomial pathogen worldwide. Antibacterial compounds produced by *Lb. acidophilus* LC1285 and *Lb. casei* LBC80R strains were active against clinical isolates of MRSA strains 43, 64, 75, 27, 61, 22, 18, 69, 80, 36 and ATCC 43300 (Karska-Wysocki et al., 2010).

Fungicidal Activity

Fresh fruits, vegetables, and also grains and nuts are rich sources of nutrition which is important for fungal growth (Bueno et al., 2004). Food spoilage by mold and the occurrence of their mycotoxins constitute a potential health hazard. Development of biological control should help improve the safety of products by controlling mycotoxin contamination (Dalié et al., 2010). LAB have a GRAS status. They have been used to ferment foods for many years, which suggest the nontoxic nature of metabolites produced by these organisms. Moreover, it is believed that the metabolic activity of LAB that may contribute in many ways to the control

of bacterial pathogens, and improvement of shelf life and sensory qualities, might also have applications for preventing mold growth (Bianchini, 2015). To date, the use of LAB and their antifungal compound for controlling growth of fungi have received much attention by researchers. The growth of *Aspergillus (A) nidulans* was inhibited during co-cultivation with *Lb. plantarum* MiLAB 393 and the expression of fungal proteins was altered. Cyclo (L-Phe–L-Pro), lactic acid and 3-phenyllactic acid were the active compounds produced by this LAB strain which affected on the growth of *A. nidulans* (Ström et al. 2005). *Lb. acidophilus* LMG 9433 suppressed the growth of *Penicillium (Pe)* spp. The supernatant of *Lb. amylovorus* DSM 20532 was fairly inhibiting for *Cerinosterus* sp., *Cladosporium* sp., *Endomyces (Ed) fibuliger* MUCL 11443, *Penicillium* spp. A, F and G and *Rhizopus (R) oryzae* MUCL 20145. With *Lb. coryniformis* subsp. *coryniformis* LMG 9196, clear inhibition zones were detected against *Cerinosterus* sp., *Cladosporium* sp., *Penicillium* spp. F and G and *R. oryzae* MUCL 20145. The antifungal properties of supernatants collected from these LAB were due to organic acids and other pH-dependent antifungal substance (De Muynck et al., 2004). Bacteriocin-synthesizing *Lc. lactis* strains 194 and K-205 were isolated from raw cow milk. These strains had high antibiotic activity against *Eurotium (Er) repens* up to 3600 and 2700 IU/mL as compared to nisin and up to 2500-1700 IU/mL as compared to fungicidal antibiotic nystatin (Stoyanova et al., 2010). *Ec. durans* A5-11 was isolated from traditional Mongolian airag cheese. This strain inhibited the growth of several fungi including *Fusarium (F) culmorum*, *Pe. roqueforti*, *Pe. expansum*, *Debaryomyces (D) hansenii*, *Candida krusei* and *Mucor plumbeus*. It produced two bacteriocins: durancin A5-11a and durancin A5-11b which contained antagonistic activity against tested *D. hansenii* strain LMSA2.11.003 (Belguesmia et al., 2012). The antifungal properties of cell-free culture filtrate (CCF) from *Lb. casei* AST18 were detected, and the antifungal compounds of CCF were found to be lactic acid, cyclo-(Leu-Pro), 2,6-diphenyl-piperidine, and 5,10-diethoxy-2,3,7,8-tetrahydro-1H,6H-dipyrrrolo[1,2-a;1',2'-d]pyrazine. The antifungal activity against *Penicillium* sp. of *Lb. casei* AST18 was a synergistic effect of lactic acid and cyclopeptides (Li et al., 2012). An anti-*Candida* protein (ACP) produced by *Ec. faecalis* showed a broad-spectrum activity against multidrug-resistant *Candida albicans* strain MTCC 183, MTCC 7315, MTCC 3958, NCIM 3557, NCIM 3471 and DI. A molecular weight of ACP was approximately 43 kDa, stable after heat-treatment at 90°C for 20 min, maintained activity over a pH range 6–10 and remained active after treatment with α -amylase, lipase, organic solvents, and detergents (Shekh & Roy 2012). Lactic, acetic and phenyllactic acids (PLA) were responsible for antifungal activity produced by *Lb. casei* CRL 239, *Lb. plantarum* CRL 681, 788, 759, 142, *Lb. fermentum* CRL 220, 236, 251, *Lb. reuteri* CRL 1098 and *Lb. acidophilus* CRL 1070. Among these strains, *Lb. fermentum* CRL 251 produced fungus inhibitory peptide/s, smaller than 10 kDa, thermostable, active in the pH range of 4-7 and sensitive to trypsin (Gerez et al., 2013). *Lb. casei*, *Lb. rhamnosus*, *Lb. fermentum*, *Lb. acidophilus*, *Lb. plantarum*, *Lb. sakei* and *Lb. reuteri* had the capabilities to produce 3-phenyllactic acid which exhibited the inhibition of *Colletotrichum gloeosporioides*, *Botrytis cinerea*, *Pe. expansum* and *A. flavus* (Cortés-Zavaleta et al., 2014). Phenyllactic, OH-phenyllactic and benzoic acids were the active compounds produced by *Lb. amylovorus* DSM 19280 and *Lb. reuteri* R29 which were active against *F. culmorum*. *Lb. amylovorus* DSM 19280 cell-free-supernatant (CFS) inhibited *F. culmorum* spores at levels of 10^4 spores/mL, for seven days, whereas *Lb. reuteri* R29 CFS inhibited up to 10^5 spores/mL for the same time (Oliveira et al., 2015). The organic acid content of crude antifungal substances produced by *Lb. sakei* ALI033 showed high

concentrations of lactic acid (502.47 mg/100 g). Antifungal substance against *Pe. brevicompactum* FI02 produced by *Lb. sakei* ALI033 is most likely due to its ability in producing organic acid (Huh & Hwang, 2016). Reuterin produced by *Lb. reuteri* ATCC 53608 showed a fungicidal activity (killed 99.9% of all tested microorganisms) against *Aspergillus* spp., *Paecilomyces* spp., *Penicillium* spp., *Candida* spp., *Aureobasidium pullulans*, *Er. rubrum/amstelodami*, *Kluyveromyces* spp., *Saccharomyces* spp., *Lachancea thermotolerance*, *Rhodotorula mucilaginosa*, *Torulospira delbrueckii*, *Wickerhamomyces anomalus*, *Zygosaccharomyces rouxii*. MICs of reuterin ranged from 1.0 to 4.8 mM (Vimont et al. 2019).

Sporicidal Activity

Control and eradication of *Bacillus* and *Clostridium* spores are one of the most challenging aspects of microbial control faced by the modern food industry. Traditionally, spores have been controlled using extreme treatments such as high heat alone or in combination with chemical additives. However, modern consumers are more conscious than previous generations of the adverse health effects associated with the consumption of certain chemical preservatives and the significant effects of heat on the nutritional value and flavor of many foods (Egan et al., 2016). Therefore, application of LAB containing sporicidal activity in medium and food model has been widely investigated. *B. cereus* cultures were inoculated into the nonfat milk medium at 0, 24, and 48 h after the growth of LAB (*Strep. lactis*, *Strep. thermophilus*, *Lb. acidophilus*, and *Lb. bulgaricus*). After 72 h of fermentation of all the tested LAB, *B. cereus* declined to less than 10 CFU/mL within 40 min. Spore germination of *B. cereus* was not affected in media that were fermented for 24 h. Germination frequencies were lowered to 33 to 43% and 23 to 27% in media fermented for 48 and 72 h, respectively (Wong et al., 1988). The bacteriocinogenic *Lb. plantarum* BN, *Lc. lactis* ATCC 11454 and *Ped. pentosaceus* ATCC 43200 and 43201 inhibited the germination of *Clostridium* (*Cl*) *botulinum* spores (10^4 spores/mL) at the incubation temperature of 4, 10, 15 and 30°C. *Lc. lactis* 11454 was the most active and was followed by *Ped. pentosaceus* 43200 and 43201 and *Lb. plantarum* BN. Increasing the bacteriocinogenic cell inoculum levels from 10^2 through 10^4 to 10^6 CFU/mL increased the radio of inhibition zones (Okereke et al., 1991). In the present work, bacteriocins produced by *Lc. lactis* subsp. *lactis* INIA 415 apparently inhibited outgrowth of *Cl. beijerinckii* spores, since spore counts remained fairly constant in cheese made from milk inoculated with this culture and clostridial spores throughout the ripening period (Garde et al., 2011). Ávila et al. (2014) reported that *Lb. reuteri* INIA P572 was used as reuterin-producing strain. Reuterin were able to inhibit the growth of vegetative cells and spores of all assayed *Clostridium* strains (*Cl. tyrobutyricum*, *Cl. butyricum*, *Cl. beijerinckii* and *Cl. sporogenes*) in milk and modified RCM broth. In milk, the MICs of reuterin suppressed the vegetative cells and spores of *Clostridium* ranged from 1.02–16.25 mM and 4.06–32.50 mM, respectively. In mRCM, the concentration of reuterin required to inhibit the growth of vegetative cells (0.51–8.13 mM) of the four tested species of *Clostridium* was lower than that required to inhibit the spores (2.03–16.25 mM). Reuterin, with a broad inhibitory activity spectrum against *Clostridium* spp. spores and vegetative cells, may be the best option to control *Clostridium* growth in dairy products and to prevent associated

spoilage, such as late blowing defect of cheese. The sensitivity of *Cl. perfringens* to reuterin which is produced by *Lb. reuteri* INIA P572, was depended on strain and culture medium. In general, vegetative cells exhibited higher sensitivity than spores. Reuterin (MIC values 2.03–16.25 mM) inhibited the growth of vegetative cells and the outgrowth of spores of all tested *Cl. perfringens*, both in mRCM and milk, with higher resistance in milk (Garde et al., 2014).

USE OF LAB WITH ANTIMICROBIAL ACTIVITY AND THEIR ANTIMICROBIALS IN FOOD AND CLINICAL APPLICATIONS

In the past, fermentation was the process used to improve the quality and shelf life of food products and the secret of their extended shelf life is the presence of antimicrobial LAB, which are natural inhabitants of fermented foods (Varsha & Nampoothiri, 2016). Then, application of pure or mixed culture of LAB as starter culture has become widespread in the industrial production of fermented food products (Brashears et al., 2005). Nowadays, the employment of LAB containing antagonism effect has extended not only in fermented foods but also in fresh and minimally processed foods. Numerous studies have shown the potential use of either LAB cells or antimicrobial compounds from them as protective cultures or biopreservatives in food products for many years. Moreover, LAB have shown to be probiotic cultures based on their GRAS status and probiotic features including antagonistic activity against pathogens, acid and bile resistance, ability to colonization on the digestive tract, immunomodulatory modulation, antimutagenic and anticarcinogenic properties (Saarela et al., 2000; Saad et al., 2013).

In the past years, there has been a particular focus on the application of bacteriocins produced by LAB in controlling the growth of pathogenic bacteria in foods. In six of the CFSs, different class IIa bacteriocins, namely leucocin A and B, mundticin L, pediocin PA-1, sakacin A, and sakacin X produced by *Leuc. carnosum* IDE1105, *Enterococcus* sp. IDE0886, *Ped. acidilactici*, *Lb. plantarum* IDE0105, *Lb. sakei* IDE0216 and *Lb. curvatus* IDE0444, respectively, were identified as the major anti-*Listeria* compounds. The minimal effective concentration (MEC) of the individual CFSs to achieve a 2.3 log₁₀ reduction of *L. monocytogenes* was determined in culture broth, whole milk, and ground beef at 4°C. Best results were obtained using CFSs containing pediocin PA-1, that displayed only three- and ten-times higher MECs in milk (307 AU/mL) and ground meat (1024 AU/g) compared to the broth, respectively. A twenty-fold increase in the MEC (2048 AU/mL) was observed for a mundticin L-containing fermentate, and a CFS containing leucocin A and B was inactivated more than fifty-fold (> 1280 AU/mL) in both food matrices. Remarkably, the sakacin A and sakacin X containing CFSs displayed very selective inactivation rates, in which sakacin A was only effective in meat (512 AU/g), while sakacin X was only effective in milk (2048 AU/mL) (Hartmann et al., 2011). Moreover, the effect of poly (lactic acid) (PLA)/sawdust particle (SP) biocomposite film incorporated with pediocin PA-1/AcH (Ped) on the reduction of *L. monocytogenes* in raw sliced pork was investigated. A model study of PLA/SP + Ped as a food-contact antimicrobial packaging on raw sliced pork suggests a potential inhibition of *L. monocytogenes* (99% of the total listerial population) on raw sliced pork during the chilled storage (Woraprayote et al., 2013). Pathogens were inoculated on freshly harvested spinach, followed by application of the LAB antimicrobial (LactiGuard™, commercial LAB product).

Treated spinach was aerobically incubated up to 12 days at 7°C and surviving pathogens enumerated via selective/differential plating. L-lactic acid and a bacteriocin-like inhibitory substance (BLIS) were detected and quantified from cell-free fermentates obtained from LAB-inoculated liquid microbiological medium. Application of 8.0 log₁₀ CFU/g LAB produced significant reductions in *E. coli* O157:H7 and *Salmonella* populations on spinach of 1.6 and 1.9 log₁₀ CFU/g, respectively (Cálix-Lara et al. 2014). Using bacteriocin-producing strains in the manufacture of fresh cheese might contribute to preventing the growth of undesirable pathogenic bacteria such as *L. monocytogenes*. Fresh cheese was made from pasteurized cows' milk inoculated with bacteriocin-producing LAB and artificially contaminated with approximately 10⁶ CFU/mL of *L. monocytogenes*. In comparison, an increase of 4 log CFU/mL in pathogen numbers in cheese was detected over the same period, in the absence of bacteriocin-producing LAB. The combination of two bacteriocin producing *Enterococcus* sp. optimized the reduction of *L. monocytogenes* counts in fresh cheese, reducing by approximately 5 log units after seven days (Coelho et al., 2014). The biopreservative effect of the cell-free supernatant containing bacteriocin on quality and shelf life of fresh pork stored for 16 days at 4°C were investigated. The antimicrobial substance could retain the good quality and extend the shelf life pork during storage and 1.2% antimicrobial substance could extend the shelf life to 12 days and the meat showed good characteristics (Miao et al., 2015). Outbreaks of food-borne disease associated with the consumption of fresh and minimally processed fruits and vegetables have increased dramatically over the last few years. Traditional chemical sanitizers are unable to completely eradicate or kill the microorganisms on fresh produce. These conditions have stimulated the search for alternative methods for increasing food safety. The use of protective cultures, particularly LAB, has been proposed for minimally processed products (Siroli et al., 2015). Applying the *Lb. plantarum* strains CIT3 and V7B3 to apples and lettuce, respectively, increased both the safety and shelf-life. The *Lb. plantarum* CIT3 strain achieved a significant inhibition of *E. coli* and *L. monocytogenes* in sliced apples. In fact, in the products inoculated with *Lb. plantarum* CIT3, the kinetics of *E. coli* death accelerated significantly and was below the limit of detection after seven days (Siroli et al., 2015). In fermented meat, *Clostridium* spp. growth is kept under control by the addition of nitrite. The growing request of consumers for safer products has led to consider alternative bio-based approaches, the use of protective cultures being one of them. When *Lb. plantarum* PCS20 (initial concentration 9 log CFU/ g) was added to the batter without nitrite treatment, a significant reduction of *Cl. perfringens* was observed between day 2 and 5 in comparison with the batch containing only the pathogen. The results from the last sampling day showed that, after nine days of the fermentation process, *Cl. perfringens* growth was inhibited to 1.5 log CFU/g in the batches inoculated with the protective culture (Di Gioia et al., 2016). *Vibrio* (*V*) *parahaemolyticus* is recognized as the main cause of gastroenteritis associated with the consumption of seafood. Bacteriocin-producing *Lb. plantarum* FGC-12 isolated from golden carp intestine had strong antibacterial activity toward *V. parahaemolyticus*. This bacteriocin showed MIC for *V. parahaemolyticus* at 6.0 mg/mL. The addition of the fish-borne bacteriocin to shrimps leaded *V. parahaemolyticus* to reduce 1.3 log units at 4 °C storage for six day (Lv et al., 2017). *Lb. curvatus* 54M16 produced bacteriocins *sak* X, *sak* T_α, *sak* T_β and *sak* P containing antibacterial activity against *L. monocytogenes*. In MRS broth, *Lb. curvatus* 54M16 was able to inhibit *L. monocytogenes* to undetectable levels after 48 h at 20°C or 5 days at 15°C. Anti-

Listeria activity was lower during the production of fermented sausages with pathogen inoculation at levels of approximately 4 log CFU/g. However, total inhibition of *L. monocytogenes* native to the raw ingredients was achieved after the fermentation period (Giello et al., 2018). *Ped. acidilactici* CRL 1753 produced phenyl-lactic acid was used as a liquid bio-preserver in bread making to increase the shelf life of wheat bread. A significant increase in shelf life was observed when CRL 1753 culture (incubated for 48 h) and calcium propionate (CP) were combined into the bread formulation; at 18 days of storage no molds were observed when the lactic strain was added while 70% of bread was spoilage in the bread made with CP alone (Bustos et al., 2018).

Dietary components such as vegetable or probiotic microorganisms have been proposed as an alternative solution to decrease *H. pylori* colonization in at-risk populations. Some strains of LAB have been shown to exert bacteriostatic or bactericidal effects against *H. pylori* in *in vitro* and *in vivo* models. The study of Cruchet et al. (2003) suggested that regular ingestion of a probiotic strain, *Lb. johnsonii* La1, may interfere with *H. pylori* colonization in asymptomatic children and may be an effective alternative to modulate *H. pylori* infection and its associated gastritis in pediatric populations with high prevalences of infection by this pathogen. The patients received the probiotic therapy (*Lb. rhamnosus* GG, *Lb. rhamnosus* LC705, *Bifidobacterium* (*B*) *breve* Bb99 and *Propionibacterium* (*P*) *freudenreichii* subsp. *shermanii* JS) or a placebo during *H. pylori* eradication and for three weeks following the treatment and their daily symptoms were recorded in a standardized diary. No significant differences were found between the two groups for individual symptoms. However, the probiotic group showed less treatment-related symptoms throughout the *H. pylori* eradication therapy in contrast to the placebo group (Myllyluoma et al., 2005). In 40 *H. pylori*-positive subjects receiving *Lb. reuteri* once a day for four weeks or placebo, *Lb. reuteri* ATCC 55730 reduces *H. pylori* load as semi-quantitatively, assessed by both ¹³C-urea breath test δ -value and *H. pylori* stool antigen quantification after four weeks of treatment ($p < 0.05$). No changes were observed in patients receiving placebo. *Lb. reuteri* administration was followed by a significant decrease in the gastrointestinal symptom as compared to pretreatment value that was not present in those receiving placebo. No difference in eradication rates was observed (Francavilla et al., 2008). In another study, people infected with *H. pylori* ingested probiotic apple snack containing 10⁸ CFU of *Lb. salivarius* subsp. *salivarius* for four weeks. A decrease in the values of ¹³C in the expired breath of subjected was observed. This probiotic strain showed the beneficial effects against *H. pylori* infection (Betoret et al., 2012). A total of 229 patients were randomly assigned to either a 1-week triple therapy of rabeprazole (10 mg bid), amoxicillin (750 mg bid), and clarithromycin (200 mg bid) or triple therapy plus *Lb. gasseri*-containing yogurt. In the yogurt-plus-triple therapy groups, yogurt containing *Lb. gasseri* OLL2716 (112 g) was given twice daily for four weeks (3 weeks pretreatment and also one week during eradication therapy). Overall eradication (intention to treat/per protocol) was 74.5% for the triple-only group, and 85.6% for the yogurt-plus-triple group. Eradication of primary clarithromycin-resistant strains tended to be higher for yogurt-plus-triple therapy than triple-only therapy (38.5 vs 28.0%, respectively) (Deguchi et al., 2012). A meta-analysis study of Fang et al. (2018) concluded that *Lactobacillus*, as an adjunct to triple therapy, can increase *H. pylori* eradication rates as well as reduce the incidence of therapy-related diarrhea in children. Moreover, a higher dose and a longer duration of supplementation may conduce to the positive impact of *Lactobacillus* on *H. pylori* eradication.

A total of 64 children with acute watery diarrhea were studied. The probiotic group received 10^8 CFU *Lb. reuteri* DSM 17938 for five days in addition to oral rehydration solution (ORS) and the second group was treated with ORS only. The mean duration of diarrhea was significantly reduced in the *Lb. reuteri* group compared to the control group (approximately 15 h, 60.4 ± 24.5 h vs. 74.3 ± 15.3 h). The percentage of children with diarrhea was lower in the *Lb. reuteri* group (13/29; 44.8%) after 48 h than the control group (27/31; 87%) (Dinleyici et al., 2015). The intervention was a 28 day, the once-daily course of a four-strain oral probiotic capsule containing *Lb. acidophilus* NCFM, *Lb. paracasei* Lpc-37, *B. lactis* Bi-07 and *B. lactis* Bl-04. Probiotic adjunct therapy was associated with a significant improvement in diarrhoea outcomes. The primary duration of diarrhoea outcome (0.0 versus 1.0 days) and two exploratory outcomes, total diarrhoea days (3.5 versus 12.0 days) and rate of diarrhoea (0.1 versus 0.3 days of diarrhoea/stool diary days submitted), all decreased in participants with probiotic use compared with placebo. There was no significant difference in the rate of *Clostridium difficile* infection (CDI) recurrence or functional improvement over time between treatment groups (Barker et al., 2017). The oral administration of *Ped. pentosaceus* LI05 improved the survival rate and alleviated the histopathological impact of *Cl. difficile* in mice. Compared to the CDI group, the levels of inflammatory mediators in the colon, as well as inflammatory cytokines and chemokines in serum, were substantially attenuated in the LI05 group (Xu et al., 2018). Over 70% of patients are prescribed antibiotics during their intensive care unit (ICU) admission. The gut microbiome is dramatically altered early in an ICU stay, increasing the risk of antibiotic-associated diarrhea (AAD) and *Cl. difficile* infections (CDI). Evidence suggests that some probiotics are effective in the primary prevention of AAD and CDI. In a recent study, where thirty-two patients participated, there were no serious adverse events in the probiotic group, compared to three in the control group. AAD was documented in 12.5% of the probiotic group and 31.3% in the control group. One patient in the probiotic group developed CDI compared to three in the control group (Alberda et al., 2018).

CONCLUSION

LAB are found in a variety of natural habitats, not only in dairy, meat, cereal, plants and their fermentative products but also in GI tract of human and animals. These niches are suitable sources for the isolation of LAB. *Lactobacillus* seems to be frequently detected in these origins. Antimicrobials such as organic acids, ethanol, fatty acids, acetoin, hydrogen peroxide, diacetyl, antifungal compounds, reuterin, reutericyclin and bacteriocins released by LAB, have significant effects against spoilage and pathogenic microorganisms which are fascinating for food and clinical applications. In consequence, LAB have extensively served as protective cultures or biopreservative agents in various food products instead of the use of chemical a method named “bio-control approach.” Based on GRAS status, LAB have also been used as probiotics which are combined with antibiotic-based therapy for treating patients suffering from some bacterial infections.

Table 3. Use of LAB and their antimicrobials in food products

Food model	Producer	Antagonistic substance	Tested bacteria	Reduction in pathogenic population	Reference
Whole milk and Ground beef	<i>Enterococcus</i> sp. IDE 0886, <i>Lb. curvatus</i> IDE 0444, <i>Lb. plantarum</i> IDE 0105, <i>Lb. sakei</i> IDE0216, <i>Leuc. carnosum</i> IDE1105, <i>Ped. acidilactici</i>	Mundticin L, sakacin X , pediocin PA-1, sakacin A, leucocin A and B pediocin PA-1	<i>L. monocytogenes</i>	2.3 log ₁₀ reduction (MEC: 2048, 2048, 307, >1280, >1280 and 307 AU/mL in whole milk MEC: 2048, >10,240, 1024, 512, >1280 and 1024 AU/mL in ground beef)	Hartmann et al. (2011)
Raw slice pork	<i>Ped. pentosaceus</i> BCC 3772	Pediocin PA-1/AcH in poly (lactic acid)/sawdust particle biocomposite film	<i>L. monocytogenes</i>	2 log cycles or 99% of total listerial population	Woraprayote et al. (2013)
Fresh spinach	LactiGuard™ (commercial LAB product)	L-Lactic acid and a bacteriocin-like substance	<i>E. coli</i> O157:H7 and <i>S. enterica</i>	1.6 and 1.9 log ₁₀ CFU/g	Cáliz-Lara et al. (2014)
Azorean artisanal cheese (Pico cheese)	<i>Lc. lactis</i> and <i>Ec. faecalis</i>	bacteriocin	<i>L. monocytogenes</i>	~ 5 log ₁₀ CFU/g	Coelho et al. (2014)
Fresh pork	<i>Lb. paracasei</i> subsp. <i>tolerans</i> FX-6	Bacteriocin with broad- spectrum	Spoilage bacteria (Total viable bacteria)	Maintain total viable count at 4 log ₁₀ CFU/g	Miao et al. (2015)
Minimally processed apples and lamb's lettuce	<i>Lb. plantarum</i> CIT3 and V7B3	-	<i>E. coli</i> and <i>L. monocytogenes</i>	below the limit of detection	Siroli et al. (2015)
Pork ground meat	<i>Lb. plantarum</i> PCS20	-	<i>Clostridium</i> spp.	1 to 1.5 log ₁₀ CFU/g	Di Gioia et al. (2016)
Shrimp (<i>Penaeus vannamei</i>)	<i>Lb. plantarum</i> FGC-12	Bacteriocin	<i>V. parahaemolyticus</i>	1.3 log ₁₀ CFU/g	Lv et al. (2017)
Fermented sausages	<i>Lb. curvatus</i> 54M16	bacteriocin	<i>L. monocytogenes</i>	<1 log ₁₀ CFU/g	Giello et al. (2018)
Wheat bread.	<i>Ped. acidilactici</i> CRL 1753	Phenyllactic acid + calcium propionate	<i>A. niger</i> CH2, <i>A. japonicus</i> CH5, <i>Pe. roqueforti</i> CH4, <i>Pe. digitatum</i> CH10 and <i>Metschnikowia pulcherrima</i> CH7	None mould observed	Bustos et al. (2018)

-; not determined. MEC, Minimal effective concentrations.

Table 4. Use of LAB containing antibacterial activity as probiotics in clinical application

Infectious disease	Products	LAB strain	Dose and duration time	Results	Reference
<i>H. pylori</i> infection	Probiotics	<i>Lb. johnsonii</i> La1	>10 ⁷ CFU/mL for 4 weeks	Regular ingestion of a product containing <i>Lactobacillus</i> La1 represent an interesting alternative to modulate <i>H. pylori</i> colonization in children	Cruchet et al. (2003)
	Probiotics	<i>Lb. rhamnosus</i> GG, <i>Lb. rhamnosus</i> LC705, <i>B. breve</i> Bb99 and <i>Propionibacterium freudenreichii</i> subsp. <i>shermanii</i> JS	10 ⁹ CFU twice a day for 13 weeks	The <i>H. pylori</i> eradication rate was non-significantly higher in the group receiving probiotic therapy compared with control group	Myllyluoma et al. (2005)
	Probiotic tablets	<i>Lb. reuteri</i> ATCC 55730	10 ⁸ CFU for 4 weeks	<i>Lb. reuteri</i> effectively suppresses <i>H. pylori</i> infection in humans and decreases the occurrence of dyspeptic symptoms.	Francavilla et al. (2008)
	Probiotic apple snack	<i>Lb. salivarius</i> subsp. <i>salivarius</i>	10 ⁸ CFU/d for 4 weeks	Decrease in the values of ¹³ C in the expired breath	Betoret et al. (2012)
	Probiotic yoghurt	<i>Lb. gasseri</i> OLL2716	≥10 ⁹ CFU twice daily for 4 weeks	Improves the efficacy of triple therapy in patients with <i>H. pylori</i> infection	Deguchi et al. (2012)
	Probiotics or yoghurt supplemented with probiotics	<i>Lactobacillus</i> spp.	-	Increase <i>H. pylori</i> eradication rates as well as reduce the incidence of therapy-related diarrhea in children	Fang et al. (2018)
<i>Clostridium difficile</i> associated diarrhea	Probiotics	<i>Lb. reuteri</i> DSM 17938	10 ⁸ CFU/d for 5 days	Significantly reduces the mean duration of diarrhea in children.	Dinleyici et al. (2015)
	Probiotics	<i>Lb. acidophilus</i> NCFM, <i>Lb. paracasei</i> Lpc-37, <i>B. lactis</i> Bi-07 and <i>B. lactis</i> Bi-04	1.7 × 10 ¹⁰ CFU/d for 4 weeks	Decrease significantly the duration of CDI diarrhea.	Barker et al. (2017)
	Probiotics	<i>Ped. pentosaceus</i> LI05	3 × 10 ⁹ CFU/d for 14 days	Reduce the risk of CDI by down-regulating the degree of intestinal inflammatory response and the production of serum inflammatory mediators, protecting the intestinal barrier function.	Xu et al. (2018)
	Probiotic yoghurt drink	<i>Lb. casei</i>	10 ⁹ CFU twice a day for 30 days	A probiotic containing drink can safely be delivered via feeding tube and should be considered as a preventative measure for AAD and CDI in ICU.	Alberda et al. (2018)

Chapter 300

DIVERSITY AND PRODUCTION OF γ -AMINOBUTYRIC ACID BY LACTIC ACID BACTERIA

Sukanya Phuengjayaem and Somboon Tanasupawat*

Department of Biochemistry and Microbiology,
Faculty of Pharmaceutical Sciences, Chulalongkorn University,
Bangkok, Thailand

ABSTRACT

Gamma-aminobutyric acid (GABA) is a non-protein amino acid, which is produced from the decarboxylation of L-glutamic acid by glutamate decarboxylase. GABA provides beneficial effects for human health, inhibiting cancer cell proliferation, helping the recovery from alcohol-related symptoms, controlling stress, improves memory and learning abilities. Therefore, it has been classified as a bioactive compound in foods and medicine. GABA was produced by various micro-organisms including fungi, yeasts and lactic acid bacteria (LAB). Currently, LAB strains are accepted for high-performance GABA production including *Lactobacillus* (*Lb*) and *Pediococcus* (*Ped*) from Nham (Thai fermented pork sausage), *Lb. senmaizukei* from traditional pickles and *Lactococcus* (*Lc*) from cheese in Japan, *Lb. paracasei* from cheese in Italy and Japanese traditional fermented fish, *Lb. brevis* from many fermented foods (Korean fermented vegetable kimchi, Chinese traditional paocai, fresh milk, alcohol distillery lees, and black raspberry juice); and *Lb. plantarum*, *Leuconostoc* (*Leuc*) and *Weissella* (*W*) from kimchi in Japan and Korea. The production of GABA by microorganisms is dependent on several factors, including pH, temperature, glutamate concentration, medium component, and cultivation time. These factors have been optimized by the one-factor-at-a-time method. The limitation of this method varies only one independent factor at a time while fixing all others, and the interactions between each factor are neglected. Eventually, response surface methodology (RSM), as a statistical method, is more rapid, reduces the number of experiments and studies interactions several factors, which saves the cost of experiment and time. The statistical RSM method will be applied.

INTRODUCTION

Gamma-aminobutyric acid (GABA) is an amino acid that consists of four carbons, nine hydrogens, two oxygens, and one molecule of nitrogen. The chemical formula is $C_4H_9NO_2$ and molecular weight of 103.12 g/mole. GABA is widely distributed in nature including microorganisms, plants and animals (Ueno, 2000). Many microorganisms such as fungi, *Monascus purpureus* (Su et al., 2003) and *Rhizopus microsporus* (Aoki et al., 2003); and LAB strains of the genera *Lactobacillus*, *Pediococcus*, *Lactococcus*, *Leuconostoc* and *Weissella* are reported to produce GABA (Dhakal, BajpaiBaek, 2012). GABA has shown several important functions in humans and animals (Foster & Kemp, 2006), therefore some high GABA-producing LAB have been emphasized for GABA production and GABA-enriched in fermented food. Furthermore, GABA or GABA-enriched in fermented food has been entering the commercial process as food additives and functional food supplements. In this chapter, GABA structure and function, diversity of GABA producing LAB, the method for the determination, improvement and development process for high yield of GABA, application, and benefits of GABA have been described.

γ -AMINOBUTYRIC ACID (GABA): STRUCTURE AND FUNCTION

GABA was first synthesized in 1883 and was known only as a plant and microbial metabolic product; however, it was found to be an integral part of the mammalian central nervous system in 1950. Until 1959, it was shown to be an inhibitory synapse on crayfish muscle fibers and GABA acted to stimulate the inhibitory nerve. Both inhibitions by nerve stimulation and the application of GABA were blocked by picrotoxin (Roth, Cooper & Bloom, 2003). GABA was decarboxylated from L-glutamic acid, catalyzed by α -glutamate decarboxylase (GAD) with pyridoxal 5' phosphate (PLP: the active form of vitamin B6) as a cofactor. This process converts irreversible alpha-decarboxylation of L-glutamate (the principal excitatory neurotransmitter) into GABA (the principal inhibitory neurotransmitter) (Figure 1).

GAD, a catalyzed enzyme for GABA, is generally discovered in eukaryotes and prokaryotes such as in microorganisms, plants, and animals. Although some GABA can be found in pancreatic cells and kidney, there is no significant amount of GABA in mammalian tissues other than in the nervous system. In addition, GABA in many foods such as tea, benikoji, and germinated brown rice also have been found (Thwe et al., 2011).

Figure 1. The decarboxylation of L-glutamic acid to GABA GAD, Glutamate decarboxylase; PLP, Pyridoxal-5'-phosphate.

GABA is an inhibitory neurotransmitter in the central nervous system of mammals by binding to specific transmembrane receptors in the plasma membrane of both presynaptic and postsynaptic neurons (Kinnersley & Turano, 2000). GABA plays a role in regulating neuronal activation in the nervous system. This binding causes the opening of ion channels to allow the flow of either negatively-charged chloride ions into the cell or positively-charged potassium ions out of the cell. This action results in a negative change in the transmembrane potential, usually causing hyperpolarization. Three typical classes of GABA receptor are known: GABA_A and GABA_C ionotropic receptors, which are ion channels themselves, and GABA_B metabotropic receptors, which are G protein-coupled receptors that open ion channels via intermediaries (G proteins) (Olsen & DeLorey, 1999).

GABA is found mostly as a zwitterion, which is when the carboxyl group deprotonated and the amino group protonated. Its conformation depended on the environments. In the gas form, a highly folded conformation is strongly favored due to the electrostatic attraction between the two functional groups. The stability is 50 kcal per mole according to quantum chemistry calculations. In the solid form, more extensively modeled variants are found at the end of the amino end and the concave form at the end of the carboxylate. This is due to the packing interactions with the neighboring molecules. In solution form, five different conformations, some folded and some extended are found as a result of solvation effects. The conformational flexibility of GABA is important for its biological function, it has been found to bind to different receptors with different conformations. Many GABA analogues with pharmaceutical applications have more rigid structures in order to control the binding better (Majumdar & Guha, 1988; Sapse, 2000).

DIVERSITY OF γ -AMINOBTYRIC ACID PRODUCING LACTIC ACID BACTERIA

GABA was produced by various microorganisms based on glutamate decarboxylase (GAD). Furthermore, LAB used for the production of GABA-enriched in fermented foods has increasingly attracted great attention due to they are safe and several health-promoting properties associated with LAB themselves (Nejati et al., 2013).

Currently, GABA production using LAB has been the focus of research (Li & Cao, 2010). LAB are getting a lot of attention because they could produce bioactive peptides, amino acids, volatile fatty acids, and lactic acid throughout the fermentation process (Lahtinen, Tuomivan & Dijken, 2011). Nonetheless, to produce functional foods with the potential of modulating the blood pressure, production of GABA and L-glutamic acid in a sustained fashion is of primary importance (Li & Cao, 2010). L-Glutamic acid serves as a precursor for the formation of GABA. Addition of glutamate to the fermentation process could have an adverse effect on the accumulation of GABA (Li & Cao, 2010). Furthermore, the addition of GABA to a food matrix is recognized to be illegal (Kim et al., 2009). With such drawbacks for the development of GABA-containing foods, incorporation of L-glutamic acid-producing LAB into the fermentation process is a great advantage.

The GABA-producing ability varies widely among the strains and some GABA-producing LAB strains have shown a great promise potential in large-scale fermentation for the production of GABA (Li et al., 2010). Some fermented products enriched in GABA using

LAB as starters such as in dairy products (Hayakawa et al., 2004), black raspberry juice (Kim et al., 2009), soy milk (Tsai et al., 2006), kimchi (Seok et al., 2008), and cheese (Nomura et al., 1998) have been developed.

Currently, *Lactobacillus* (*Lb*), *Pediococcus* (*Ped*), *Lactococcus* (*Lc*), *Leuconostoc* (*Leuc*), *Streptococcus* (*Strep*), and *Weissella* (*W*) strains including *Lb. plantarum*, *Leuc. mesenteroides*, *W. cibaria*, *Lb. paracasei*, *Lb. brevis*, *Lb. casei*, *Lb. pseudomesenteroides*, *Lc. lactis*, *Lb. delbrueckii* sub sp. *bulgaricus*, *Lb. rhamnosus*, *Strep. thermophilus* and *Enterococcus* (*Ec*) *durans* has been accepted for high performance GABA production (Dhakal, BajpaiBaek, 2012). They were isolated and screened from traditional fermented food. *Lb. namurensis* NH2 and *Ped. pentosaceus* HN8 were isolated from Nham (Thai fermented pork sausage) (Ratanaburee et al., 2013). *Lb. senmaizukei* was isolated from traditional pickles kimchi (Hiraga et al., 2008). *Lb. rhamnosus* YS9 was isolated from Chinese traditional food (Lin, 2013). *Lb. paracasei* was isolated from cheese in Italy and Japanese traditional fermented fish (Komatsuzaki et al., 2005). *Lb. buchneri* and *Lb. brevis* were isolated from many fermented foods including Korean fermented vegetable kimchi, Chinese traditional paocai, fresh milk, alcohol distillery lees and black raspberry juice (Kim et al., 2009; Park & Oh 2006). The strains of *Lb. senmaizukei* from pickles (Park & Oh, 2006). *Lb. plantarum*, *Leuc. mesenteroides*, *Leuc. lactis* and *W. viridescens* were isolated from kimchi in Japan and Korea (Kim & Kim, 2012). *Lc. lactis* strains were isolated from cheese starters and cheese in Japan (Lu et al., 2008; Nomura et al., 1998). Moreover, LAB were isolated from black raspberry juice and soymilk (Tsai et al., 2006). The high GABA producing strains, *Lb. paracasei* PF6, *Lb. delbrueckii* sub sp. *bulgaricus* PR1, *Lc. lactis* PU1 and *Lb. brevis* PM17 have been isolated from Pecorino di Filiano, Pecorino del Reatino, Pecorino Umbro, and Pecorino Marchigiano cheeses in Italy, respectively (Siragusa et al., 2007).

Multitudinous of GABA-producing LAB are important for the food industry (Komatsuzaki et al., 2005). Because of the potential for producing GABA-enriched foods, LAB are received a lot of attention. The ability of LAB to produce GABA is varied among species and the strains as shown in Table 1.

Table 1. GABA produced by lactic acid bacteria

Strain	Source	Medium	GABA Yield	Time (h)	Reference
<i>Bifidobacterium dentium</i> NFBC2243, DPC6333 and UCC35624	Dental carries, Infant feces and ileal-caecal region	MRS with 5% (w/v) MSG	8.63, 6.16 and 2.04 g/L	48	Barrett, 2014
Co-fermented with <i>Leuc. mesenteroides</i> SM and <i>Lb. plantarum</i> K154	Carrot juice and kimchi	MRS with 3% (w/v) MSG	10 mg/ml	30	Kwon et al., 2016
<i>Ec. faecium</i> NCIM 5593	Takarishita	Rice flour medium (3% w/v) with 1% (w/v) glutamate	750.55 mg/100g DM	48	Divyashri & Prapulla, 2016
<i>Lb. brevis</i> CECT 8183	Goat cheese	Sourdough medium	0.96 mM	24	Diana et al., 2014
<i>Lb. brevis</i> CRL 1942	Quinoa sourdough	MRS with 270 mM MSG	255 mM	48	Villegas et al., 2016
<i>Lb. brevis</i> GABA100	-	Black raspberry juice with 2% (w/v) MSG	26.5 mg/ml	12 day	Kim et al., 2009
<i>Lb. brevis</i> HYE1	Kimchi	MRS with 1% (w/v) MSG	18.76 mM	48	Lim et al., 2017
<i>Lb. brevis</i> NCL912	Paocai (Chinese fermented vegetable)	MRS with 134.45 mM glutamate	1005.81 mM	48	Li et al., 2010

Strain	Source	Medium	GABA Yield	Time (h)	Reference
<i>Lb. brevis</i> NPS-QW-145, NPS-QW-171, NPS-QW-177, NPS-QW-193, NPS-QW-216, NPS-QW-242, NPS-QW-255 and NPS-QW-267	Korean kimchi	MRS with 7% (w/v) MSG	25.831, 19.631, 24.098, 23.33, 21.694, 22.986, 19.072, and 24.992 g/L, respectively	72	Wu & Shah, 2015
<i>Lb. brevis</i> TCCC 13007	Pickled Chinese vegetables	3.6 g corn steep liquor, 22 g glucose, 15 g yeast extract, 2 g sodium acetate, 0.2 g MgSO ₄ , 0.2 g (NH ₄) ₂ SO ₄ with 7% (w/v) MSG	61 g/L	66	Zhang et al., 2012
<i>Lb. buchneri</i> WPZ001	Fermented sausages	MRS, Corncob hydrolysate with 0.1% MSG	129 g/L, 117 g/L	48	Zhao et al., 2015
<i>Lb. bulgaricus</i> CFR 2028	CFTRI culture collection centre	MRS with 1 % (w/v) MSG	22.7 mM	48	Gangaraju, Murty & Prapulla, 2014
<i>Lb. paracasei</i> 15C	Nostrano-cheeses	MRS	14.8 mg/kg	24	Franciosi et al., 2015
<i>Lb. paracasei</i> NFRI 7415	Fermented fish (funa-sushi)	MRS with 500 mM glutamate	302 mM	144	Komatsuzaki et al., 2005
<i>Lb. plantarum</i> MNZ	Malaysian fermented foods	MRS with 5% (w/v) MSG	115.2 mg/kg dosa	120	Zareian et al., 2015
<i>Lb. plantarum</i> NDC75017	Fermented dairy products in China	MRS with 80 mM MSG	314.56 mg/100 g substrate	-	Shan et al., 2015
<i>Lb. plantarum</i> Taj-Apis362	Honeybees	MRS with 497.97 mM of glutamate	7.15 mM	60	Tajabadi et al., 2015
<i>Lb. rhamnosus</i> 21D-B	Nostrano-cheeses	MRS with vancomycin 8 μ g/mL	11.3 mg/kg	24	Franciosi et al., 2015
<i>Lb. rhamnosus</i> GG	Bioresource and Collection Center	MRS with 2.27% (w/v) MSG	1.13 mg/mL	36	Song & Yu, 2018
<i>Lb. rhamnosus</i> YS9	Chinese pickles	MRS with 200 mM glutamate	187 mM	84	Lin, 2013
<i>Lb. senmaizukei</i> L13	Japanese pickles	GYP with 5%MSG	Not report	48	Hiraga et al., 2008
<i>Lc. lactis</i> subsp. <i>lactis</i>	Kimchi	MRS with 1% MSG	3.68 g/L	48	Lu et al., 2008
<i>Lc. lactis</i> subsp. <i>lactis</i> B	Kimchi and yoghurt	MRS with 1% (w/v) MSG, brown rice juice, germinated soybean juice and skim milk (33:58:9, v/v/v)	3.68 g/L, 6410 mg/l	48	Lu et al., 2008
<i>Lc. lactis</i> subsp. <i>lactis</i> PU1	Cheese	Wheat flour sourdough	258.71 mg/kg	48	Rizzello et al., 2008
<i>Monascus purpureus</i> CMU001	-	Rice	28370 mg/kg	7 days	Jannoey et al., 2010
<i>Ped. pentosaceus</i> NH102	Fermented pork	MRS with 0.5% (w/v) MSG	8.386 g/L	24	Ratanaburee et al., 2013)
<i>Ped. pentosaceus</i> HN8	Fermented beef	MRS with 0.5% (w/v) MSG	9.06 g/L	24	Ratanaburee et al., 2013
<i>Ped. pentosaceus</i> HN8 and <i>Lb. namurensis</i> NH2	Fermented meat (Nham)	MRS with 0.5% (w/v) MSG	4051 mg/kg	48	Ratanaburee et al., 2013
<i>Strep. thermophilus</i> 84C	Nostrano-cheeses	M17	80.0 mg/kg	24	Franciosi et al., 2015
<i>Strep. thermophilus</i> ST110	Yogurt starter	Tryptone, yeast extract-lactose (TYL) with 100 mM MSG	655 mg/L	16	Somkuri et al., 2012

MSG, Monosodium glutamate; MRS, de Man, Rogosa and Sharpe.

Although there have been many studies on GABA production by LAB, the isolation of GABA-producing LAB and the development of their GABA production need to be further explored since fermented foods as the isolation sources for GABA producers have various kinds and diverse LAB (Lim et al., 2017).

METHODS FOR THE DETERMINATION OF γ -AMINOBUTYRIC ACID

The monitoring of GABA production can be determined using several techniques, including qualitative and quantitative analysis. Thin layer chromatography (TLC) is the most primary screening method for GABA qualitative analysis. This method is simple, rapid and does not require the derivatization process for GABA, but TLC method does not provide enough accuracy for quantifying GABA. Therefore, it is only an initial analysis and requires other techniques to confirm the results. Following derivatization, GABA is measured using High-performance liquid chromatography (HPLC). This technique is extremely rapid, efficient and can be analyzed both qualitatively and quantitatively. However, it was necessary to derivative the sample before being analyzed using HPLC. Many studies usually combine TLC and HPLC methods together to evaluate and quantify GABA. The detailed analysis is summarized in Table 2.

Table 2. Determination of GABA using TLC and HPLC

TLC technique	HPLC technique		Reference
	Derivative	Condition	
-	Phenylisothiocyanate (PITC)	MP , 60% solution A (10.2 g sodium acetate, 0.5 ml triethylamine and 0.7 mL acetic acid in 1 L), 12% solution B (acetonitrile) and 28% solution C (water); Column , C18; Flow rate , 0.6 ml/min; Temp , 27°C; Detector , UV at 254 nm	Zareian et al., 2015
SP , silica gel plate; MP , n-butyl alcohol: glacial acetic acid: DW(distilled water) (3:1:1 v/v/v); Visualization , 0.2% ninhydrin in acetone, heat at 105°C	Phenylisothiocyanate (PITC)	MP , 100% Solvent A (140 mM sodium acetate, 0.15% triethylamine, 0.03% EDTA, 6% acetonitrile) and ending at 100%; Solvent B (60% acetonitrile, 0.015% EDTA), during 30 min; Column , C18; Flow rate , 1.0 ml/min; Detector , UV at 254 nm	Kwon et al., 2016
SP , silica gel plate; MP , 1-butanol: acetic acid: distilled water (3:2:1 v/v/v); Visualization , 0.5% (w/v) ninhydrin and exposing the plates to a heat source	Phenylisothiocyanate (PITC)	MP , 80% solution A (1.4 mM sodium acetate, 0.1% triethylamine, and 6% acetonitrile) and 20% solution B (60% acetonitrile); Column , Cosmosil 5C18-AR-II; Flow rate , 1.0 ml/min; Temp , 27°C; Detector , UV at 254 nm	Kim & Kim, 2012
SP , silica gel plate; MP , acetic acid:1-butanol:distilled water (1:4:5 v/v/v); Visualization , 0.2% (w/v) ninhydrin	Ortho-phthalaldehyde-mercaptoethanol	MP , sodium acetate (1.64 g) and triethylamine (200 μ l) in 1 L (20%, v/v acetonitrile); Column , Hypersil ODS; Flow rate , 0.8 ml/min; Temp , 30°C; Detector , UV at 338 nm	Kangaraju, Murty & Prapulla, 2014
SP , silica gel plate; MP , n-butanol:acetic acid:distilled water (5:3:2); Visualization , 0.4% (w/v) ninhydrin then heated to visualize the spots	O-phthalaldehyde 3-mercaptopropionic acid (OPA-3MPA)	MP , solution A (40 mM monosodium phosphate) and solution B (acetonitrile: methanol:H ₂ O; 45:45:10 (v/v/v)); Column , Hypersil ODS C18 reverse phase; Flow rate ; 1.0 ml/min; Temp , 40°C; Detector , Fluorescence detector with excitation at 340 nm, emission at 450 nm	Villegas et al., 2016

Table 3. The advantage and disadvantage of GABA determination methods

Determination Methods	Advantage	Disadvantage	Reference
Thin layer chromatography	Expedient, rapid and accurate, not require the derivatization process	Not quantitative analysis, requires a number of plates and a large volume of solvents	Kim & Kim, 2012; Kwon et al., 2016
Gas chromatography	Rapid and accurate quantitative and qualitative measurements	High cost of machine, non-volatile matrices, requires additional derivatives, an experienced technician, and be careful in using gas	Kagan et al., 2008
Gas chromatography-Mass spectrometry	Rapid and accurate, strong analytical tool, good technique for simple mixtures, accurate quantitative and qualitative	High cost of machine and requires an experienced technician	Lim et al., 2017
HPLC	Rapid and accurate, accurate quantitative and qualitative	High cost of machine and derivatives method, time consuming for sample derivatives	Zareian et al., 201; Kwon et al., 2016; Kim & Kim, 2012
Gas release-based assays	Rapid, not require the derivatization process	Expensive, not a completely accurate method to identify high GABA	Wu & Shah, 2015
pH indicator method	Expedient and rapid, not require the derivatization process	Using mechanism only, not detect the quantitative analysis	Yang et al., 2006
Enzyme assay	Specific technique, easily measurable reaction	Complicate and expensive reaction	Barla et al., 2016
Amino acid analyzer (AAA)	Expedient and rapid	Using mechanism only, high cost of machine	Lu et al., 2008; Barla et al., 2016; Chung et al., 2009
Liquid chromatography (LC)	Accurate and detect in qualitative and quantitative technic	Expensive, not portable, requires an experienced technician, and only moderate throughput	Wu & Shah, 2017; Dhakal, Bajpai & Baek, 2012
Electrospray tandem mass spectroscopy (ESI-MS)	For biological samples analysis, high amount of accuracy, accurate quantitative and qualitative measurements	Cannot analyze mixtures very well, difficult to clean and the multiple charges attached to the molecular ions will make confusing for spectral data	Gangaraju, Murty & Prapulla, 2014

Although TLC is the first choice for screening of GABA producers, it also has some limitations such as requirement of many plates and a large volume of solvents (Li et al., 2010). In addition, pre-screening methods are normally developed based on the decarboxylation of glutamate into GABA by glutamate decarboxylase; this reaction eliminates a proton and also produces carbon dioxide. Spectrophotometry assay involves using GABase enzyme. Thus, glutamate decarboxylase-based microtiter plate assay (Tsukatani, Higuchi & Matsumoto, 2005), pH indicator method (Yang et al., 2006) and gas release-based assays are suitable for high-throughput pre-screening of GABA producers with remarkable improvements in testing time and economic practice (Wu & Shah, 2015). Moreover, chromatography-based techniques such as amino acid analyzer (AAA), liquid chromatography (LC), gas chromatography (GC), are also an alternative for determining GABA amounts in many kinds of food samples (Li et al., 2010). The distinctive of AAA is does not require the derivatization process prior to analysis. LC method normally requires pre-column derivatization with dansyl chloride by an addition of chromophore to GABA that could be detected by fluorescence spectroscopy (Wu & Shah, 2015). For GC method, pre-column derivatization of GABA is usually achieved with norvaline to form a volatile compound, which could be separated and detected by GC equipped with a flame ionization detector (FID) or mass spectrometry (MS) (Kagan et al., 2008) and Gas chromatography-mass spectrometry (GC-MS) (Lim et al., 2017). The above methods are time-consuming due to tedious sample preparation processes according to analytical protocols; this requires high work-load for screening GABA-producing microorganisms and is neither economical nor rapid. Hence, a pre-screening method is necessary for identifying GABA producers prior to determining their capability to produce GABA by chromatography-based methods (Kim & Kim, 2012). The advantages and disadvantages of each technique mentioned above are summarized in Table 3.

IMPROVEMENT OF γ -AMINO BUTYRIC ACID PRODUCTION

The optimum conditions vary among the fermenting microorganisms due to the different properties of the GAD, characterization of the biochemical properties of the GAD will be required in the interested microorganisms to achieve the highest GABA production. Several fermentation factors affect the rate of GABA production by microorganisms are summarized below, especially on the effects of pH, temperature, cultivation time, glutamate concentration, and media additives of culture.

Effect of pH on GABA Production

LAB produce lactic acid as the end product through a variety of carbohydrate catabolism including Embden-Meyerhof-Parnas (EMP), Leloir pathways and pentose phosphate pathways (Kandler, 1983). This acidic environment causing LAB to be acid resistant and also GABA is an amino acid as the end product of the decarboxylation of glutamic acid, therefore this acid-resistant property has benefit for their high GABA production.

The important role of bacterial amino acids decarboxylase occurred in LAB resulted in the stoichiometric including considered regulate of acidic pH by utilization of proton ions and produced GABA as the end product, also the net effect of this reaction increases the alkalinity of the cytosol and environment (De Biase et al., 1999).

GABA production was depended on GAD and the highest yield of GABA might be obtained when the cultivation conditions were the same as that of enzyme catalysis. However, decarboxylase reaction was not enhanced under lower pH 4 (Komatsuzaki et al., 2005). In another report, the optimum of pH 5.0 which showed the highest GABA production of 1005.81 mM was obtained from *Lb. brevis* NCL912, while the cell growth was inhibited at pH 3.0 and the cell mass was decreased at pH 6.0, resulting in no GABA production. The higher or lower pH may lead to the partial loss of the GAD activity therefore, pH affected significantly on the production of biomass and GABA of *Lb. brevis* NCL912 (Li et al., 2010). Similarly, the optimum pH for GAD activity on extracellular GABA production from *Lb. paracasei* NFRI 7415 was 5.0. The glutamate content 500 mM with the addition of PLP in the culture medium was converted to 302 mM (Komatsuzaki et al., 2005). The GABA production by *Strep. salivarius* subsp. *thermophilus* Y2 was also enhanced by optimizing fermentation at pH 4.5 and by the addition of PLP (Yang et al., 2008). For the GAD of *Lb. rhamnosus* YS9, the optimal pH was determined by the measurement of enzyme activity in cells under various pH conditions. GAD activity dramatically decreased at pH 4.0 than pH more than 4.8. *Lb. rhamnosus* YS9 did not show high GAD activity at low pH, although it was believed that bacterial GAD plays a key role in the acid-resistance mechanism. The optimum pH for GAD activity was 4.4. Accordingly, GABA production was measured by *Lb. rhamnosus* YS9 under pH-regulated conditions at 43°C, 200 μ M PLP, and 200 mM MSG), *Lb. rhamnosus* YS9 produced the maximum to 187 mM of GABA by *Lb. rhamnosus* YS9 at pH 4.4, which might be due to the pH condition consistent with the optimal pH for GAD activity (Lin, 2013).

Also, there are many studies that support the effect of pH values for maintaining the activity of LAB. GAD exhibited activity ranged from 4.0 to 5.0 (Komatsuzaki et al., 2008; Huang et al., 2007; Ueno et al., 1997). It was reported that pH affected on the GABA production in LAB (Yang et al., 2008; Komatsuzaki et al., 2005; Li et al., 2010).

Effect of Temperature on GABA Production

The cell growth of *Lb. brevis* NCL912 increased when temperature was increased and the maximum was at 35°C (Li et al., 2010). Likewise, production of GABA was a similar profile to cell growth. This phenomenon could be explained that high cell density was required for effective production of GABA. Nevertheless, GABA concentration at 30°C was almost the same to that at 35°C, but biomass at 30°C was less than that at 35°C. In addition, *Lb. brevis* NCL912 could not produce GABA at 45°C while the strain could grow at this temperature. Accordingly, the production of GABA by *Lb. paracasei* NFRI 7415 was increased rapidly at 37°C but GABA production and growth rate were drastically inhibited at 43°C. These results suggested that 37°C was optimum condition for GABA production by *Lb. paracasei* NFRI 7415 (Komatsuzaki et al., 2005). On the other hand, the optimal cultivation temperature of *Lb. rhamnosus* YS9 for GABA production was 43°C (Lin, 2013), which would dramatically

inhibit other LAB's growth rate, such as *Lb. paracasei* NFRI 7415 (Komatsuzaki et al., 2005) and *Lb. brevis* NCL912 (Li et al., 2010). This might be due to the different physiological and enzymatic character (Lin, 2013). The results from the above reports indicated that appropriate temperature is beneficial to produce GABA, and excessively high temperature is unfavorable to the GABA production; and high efficient conversion glutamate to GABA required not only high growth rate but also appropriate temperature.

Effect of Glutamate Concentration on GABA Production

LAB fermented monosaccharide to produce a low molecular organic acid, resulting in acidic conditions to inhibit the growing bacteria. However, some LAB employed glutamic acid decarboxylase (GAD) system for maintaining neutral cytoplasmic pH when the external pH decreased because the decarboxylation of glutamate within the LAB cell exterminates an intracellular proton. Comparison of the adding and not adding glutamic acid appeared that the pH value of the culture without glutamate decreased to 3.4 after 24 h of fermentation by *Lb. brevis* NCL912 while pH values of the cultures supplemented with glutamate were maintained at 5.0. This indicated that GAD system of *Lb. brevis* NCL912 acted under low pH and resulted in an increase of pH in the medium by glutamate, and protected cell survival from the acidic condition. However, the extra high concentration of glutamate was harmful to the cell growth (over 0.5 M). Therefore the concentration of glutamate was optimum in the range of 0.25-0.50 M for the cell growth and GABA production by *Lb. brevis* NCL912 (Li et al., 2010). The optimum of MSG for extracellular and intracellular GABA content produced by *Lb. rhamnosus* YS9 was 100 mM at 37°C (Lin, 2013).

Effect of PLP Addition on Extracellular GABA Production

PLP, a GAD coenzyme is necessary in decarboxylation reaction. Therefore, an addition of PLP to the medium could be increased GAD activity to enhance the GABA production (Tong et al., 2002). The appropriate concentration of PLP added to the culture medium was 200 µM gave the maximum of GABA to 187 mM ((Lin, 2013). The higher concentration of PLP, resulted in higher extracellular released of GABA by *Lb. rhamnosus* YS9. The result according to the previous research of Komatsuzaki et al. (2005), when 10 µM PLP was added at initial cultivation, the GABA production was enhanced by *Lb. paracasei* NFRI 7415 and even though 100 µM PLP was added in the medium, it did not strongly inhibit the cell growth. However, this was different from that observed with *Strep. thermophilus* Y2 (Yang et al., 2008) and *Lb. brevis* NCL912 (Li et al., 2010). Consequently, it could not be concluded that the PLP will always promote GABA accumulation by LAB because some researchers reported that the addition of PLP did not affected on cell growth and not increased GABA production by *Lb. brevis* NCL912 (Li et al., 2010). They explained that the strain *Lb. brevis* NCL912 could synthesize sufficient PLP for themselves.

Effect of Cultivation Time

GABA is a growth associate product, therefore, the cultivation time has an effect on the production. LAB strains have different growth profiles depending on their biochemical properties. The main isolates from cheese produced GABA under fermentation conditions at 30°C and pH 4.7 for 24 h (Seok et al., 2008). Among the strains, GABA was produced within 24-60 h as described in Table 1.

The production of GABA by the microorganism is depended on several factors, including pH, temperature, glutamate concentration, medium component, and cultivation time. The primary objective of LAB fermentation is the highest yielding of the target product. The factors of the physical and medium component have been optimized by conventional or statistical methods, providing basic information to develop the bioprocess for commercial GABA production (Kumar & Satyanarayana, 2007). The most significant stages in the biological process are modeling and optimization to improve a system and increase the efficiency of the process. The biochemical differences of the species used for the optimal condition for GABA production are different as discussed above. Therefore, the optimum conditions vary among the fermenting microorganisms due to the different properties of the GAD. Currently, a single variable optimization design used as the first step was efficient for identifying which the ranges of fermentation factors, had a significant effect on the GABA production. The response surface methodology was used to optimize the fermentative parameter for the high production of GABA (Tajabadi et al., 2015).

The conventional method is the one-factor-at-a-time (OFAT) method. The limitation of OFAT method varies only one independent factor at a time while fixing all the other interactions between each factor are neglected resulting in just local optimum points being obtained. Eventually, response surface methodology (RSM), as a statistical method, uses an experimental design to obtain the optimum point of response, and experiments can be easily organized and translated using efficient design. In addition, RSM is more rapid, reduces the number of experiments and considering interactions between each factor, which saves the cost of experiment and time (Lim et al., 2017).

The optimizations of GABA production by LAB have focused on the conventional determination of optimal pH, temperature, PLP and glutamate concentration (Komatsuzaki et al., 2005; Li et al., 2010; Lin, 2013). Although the statistical RSM method is more efficient compared with the conventional OFAT method, there have been a few studies on the optimization for GABA production via the RSM method.

The optimum condition for GABA production by *Ped. pentosaceus* HN8 and *Lb. namurensis* NH2 using the Central Composite Design (CCD) has been reported (Ratanaburee et al., 2013) using 0.5% (w/v) MSG, inoculum size of roughly 6 log CFU/g of each two strains. The GABA production gave the maximum of 4051 mg/kg in the 'GABA Nham' product. Using the same experimental design, CCD of RSM was used to define conditions for maximum GABA production by *Lb. plantarum* Taj-Apis362. The maximum GABA of 7.15 mM was obtained under 497.97 mM of MSG, 36°C, at pH 5.31, and 60 h for cultivation time (Tajabadi et al., 2015).

In addition, the Box-Behnken Design (BBD) of RSM was used to optimize GABA production by *Lb. brevis* HYE1. The optimum conditions for maximum GABA production of 18.76 mM were obtained using 2.14% (w/v) maltose, 4.01% (w/v) tryptone, 2.38% (w/v)

MSG, and pH 4.74 (Lim et al., 2017). This was similar to the results using BBD of RSM to optimize 3 variables such as level of MSG, PLP, and culture temperature for GABA production by *Lb. plantarum* NDC75017 (Shan et al., 2015). The optimal conditions were 80 mM of MSG, 18 μ M of PLP, and temperature of 36°C, gave the maximum GABA to 314.56 mg/100 g. *Lb. plantarum* NDC75017 was a commercial starter culture that produced high GABA production in fermented yogurt. Recently, the adzuki bean milk inoculated with *Lb. rhamnosus* GG increased GABA from 0.05 mg/mL to 1.13 mg/mL after 36 h optimized by RSM, using 1.44% galactose, 2.27% MSG, and 0.20% PLP. The GABA production was increased higher than 22.4 times compared to unfermented adzuki bean milk (Song & Yu, 2018).

The secondary objective is improvement and development of the GABA production process concerning the cost-effectiveness and simple production of bio-products. It is important to select a proper process that allows of the highest yielding of the target product. For batch fermentation systems, the substrate should be put in the tank once only from the start fermentation. The limitation is that the higher initial concentration of fermentation substrate which inhibit the cell growth or residual material resources and the higher yield of product resulted in the product inhibition effect. Consequently, fed-batch fermentation system, one or more components are supplied to the fermenter while cells and products remain in the tank until the end of the operation. The optimum starting substrate concentrations, which solves the problem of substrate inhibition, and limiting fermentation can be added by feeding in the fermentation course. It may be an improvement to obtain a high yield and productivity (Krause et al., 2010). Fed-batch fermentations was used for GABA production by *Lb. brevis* NCL912 at pH, temperature, and initial glutamate concentration was fixed at 32°C, pH 5.0 and 400 mM, respectively and after 280.70 g (1.5 mol) and 224.56 g (1.2 mol) glutamate were supplemented into the bioreactor at 12 h and 24 h, respectively. Under the selected fermentation conditions, GABA was rapidly produced at 36 h other than in stationary phase. The GABA concentration was improved to 1005.81 mM, and the residual glucose and glutamate were 15.28 g/L and 134.45 mM at 48 h (Li et al., 2010). Furthermore, GABA concentration in fed-batch fermentation was improved from 660 mM to 1000 mM by *Lb. brevis* B3-18 in the batch fermentation (Kook & Cho, 2013). These experiments showed that a simple and effective fed-batch fermentation method was developed for GABA production by LAB.

APPLICATION AND BENEFITS OF GABA

The available amount of GABA normally has major inhibitory neurotransmitters in the sympathetic nervous system (Mody et al., 1994) and plays an important role in cardiovascular function (DeFeudis, 1983). Moreover, physiological action of GABA includes induction of hypotensive, diuretic effects, tranquilizer effects, prevention of diabetic conditions in humans, anterograde amnesia and retrograde amnesia and anti-convulsive effects (Wong, Bottiglieri & Snead, 2003). GABA provides beneficial effects for human health, treatments for sleeplessness, depression, autonomic disorders (Okada et al., 2000), inhibits development of cancer cells, helping the recovery from chronic alcohol-related symptoms, controlling stress and lipid levels in serum because it promotes fat loss by the stimulation of human growth

hormone production, treatment of anxiety disorders, lowers blood pressure, boosts immune system (Oh & Oh, 2003), antihypertension, anticancer, anti-inflammatory and anti-hepatitis agents (Kang et al., 2011; Ali et al., 2013). In addition, GABA increases a strong secret of insulin from the pancreas and may prevent diabetic conditions (Adeghate & Ponery, 2002) and has preventive effects on Alzheimer's disease such as amnesia and dementia; also it improves memory and the learning abilities (Nakashima et al., 2009).

These multiple benefits of GABA on human health have led to the development of GABA-enriched fermented foods, a bioactive component, a primary element of food ingredients, and application in pharmaceuticals (Kim & Kim, 2012). For GABA in food enrichment, there is an idea of producing GABA-rich wheat germ food in normal daily consumption in a relatively large population that can be beneficial to those suffering pain from chronic hypertension. Several GABA-enriched functional foods are currently manufactured such as tea leaves treated anaerobically, rice germ soaked in water, red mold rice, tempeh-like fermented soybeans, and dairy products such as yogurt, fermented milk products and cheese (Thwe et al., 2011). Therefore, great efforts are focused on mass production of GABA and its utilization as a bioactive food ingredient in the modern food industry (Kim & Kim, 2012). GABA-enriched fermented food can reduce blood pressure after consuming such products (Inoue et al., 2003). It is worth noting that the human body can generally produce its own supply of GABA; however, GABA production is inhibited by an extra amount of salicylic acid or food additives or by the lack of vitamins, zinc or estrogen (Tenpaku, 1997). Therefore, GABA enriched food is required because the GABA content in typical human diets is relatively low.

GABA-enriched fermented foods with LAB included yogurt and cheese (Park & Oh, 2006; Nomura et al., 1998), sourdough (Diana et al., 2014) and kimchi (Seok et al., 2008). The highest content of GABA was found in Pecorino di Filiano (391 mg/kg) among 22 different varieties of Italian cheeses, in which the responsible microorganisms for the GABA production were *Lb. paracasei* PF6, PF8, and PF13, *Lb. plantarum* PF14, *Lactobacillus* sp. PF7 (Siragusa et al., 2007). In shochu distillery-lees, a Japanese distilled alcoholic beverage, most of the free glutamic acid (10.50 mM) was converted to GABA (10.18 mM) by *Lb. brevis* IFO-12005 (Yokoyama, Hiramatsu & Hayakawa, 2002). GABA-enriched grape-free grape preparation must beverage, which has a potential anti-hypertensive effect and dermatological protection was manufactured by fermentation using *Lb. plantarum* DSM19463 (Di Cagno et al., 2010). In addition, (Zareian et al., 2015) reported that biosynthesis activities for the production of glutamic acid and GABA in the fermentation of dosa (contains wheat and flour, a carbohydrate-rich food) by *Lb. plantarum* MNZ provided a GABA-enhanced functional food such as antihypertensive effects on spontaneously hypertensive.

However, the direct addition of chemical GABA to food is considered unnatural and unsafe. So it is necessary to find a natural method to produce an increase GABA in food with safely and effectively. Therefore, great efforts are focused on mass production of GABA and its utilization as a bioactive food ingredient in the modern food industry (Kim & Kim, 2012).

CONCLUSION

Numerous functions of GABA are summarized to develop foods enrichment, pharmaceutical and to provide the natural products. Therefore, the production of GABA by LAB is interesting; however, many factors have been shown to affect microbial GABA production that is dependent on their biochemical properties and GAD. Also, the optimization of many factors including pH, temperature, medium component, medium concentration and cultivation time is required; thus the first step is to define the appropriate conditions to improve a high yield of GABA by microorganisms. Currently, the conventional method and statistical method are used for optimization condition. Furthermore, the second is the improvement and development of the GABA production process taking into account the cost-effective and simple production of bio-products. This type of fermentation including batch and fed-batch are compared. All these processes will lead to the higher expedient of microbial fermentation for universal applications of GABA.

ABSTRACT

DNA vaccines, which consist of plasmids encoding antigens of interest, emerge as novel options to protect hosts against new emerging infectious diseases. As most pathogens affect or initiate their infection at mucosal surfaces, this is a strategic route to induce specific immune responses. However, to make it possible, many environmental barriers must be surpassed. In this context, the use of bacteria, like *Lactococcus lactis*, as vehicles to deliver vaccine plasmids by the mucosal route is a promising strategy. Native *Lc. lactis* was used for this purpose and, aiming to make the plasmid delivery more efficient, invasive recombinant *Lc. lactis* strains were constructed and tested, thus showing to be able to deliver DNA vaccines more efficiently than the wild type strain. Therefore, in summary, this chapter presents a general view of DNA vaccines and the use of bacteria, especially *Lc. lactis*, to deliver them to intestinal eukaryotic cells, representing a new strategy for the tuberculosis control.

INTRODUCTION

Vaccination stimulates the development of immune responses to avoid infection and protect the individual from establishing a disease. Many diseases like tetanus, diphtheria,

polio and hepatitis A and B have decreased significantly with the advent of vaccines (Roush et al., 2007). However, emerging infectious diseases have become challenges to be faced by the vaccinology field and new strategies must be developed to produce more efficient vaccines to protect the population worldwide. Within this scenario, DNA vaccines emerge as good alternatives to invest time and efforts, as they may be a way to overcome these new obstacles. DNA vaccines consist of eukaryotic expression plasmids that have the coding sequence of an antigen of interest inserted into their multiple cloning sites. Although different administration routes exist, the goal of these vaccines is that the plasmid DNA reaches the host cell nucleus so that it can be transcribed, translated and expressed by the eukaryotic cell and, in this way, elicit the expected immune responses (Pereira et al., 2014).

The first findings that reported about the potential of vaccines occurred in 1990, when Wolf and colleagues injected a DNA plasmid containing the coding sequence of β -galactosidase and verified the expression of this protein in quadriceps muscle sections of mice (Wolf et al., 1990). In 1992, after injecting a plasmid encoding the human growth hormone (hGH) into mice's skin, Tang and colleagues observed the production of specific antibodies against the protein, indicating that the injected DNA was expressed and elicited a specific humoral immune response (Tang et al., 1992). Subsequently, in 1993, two independent research groups vaccinated mice with DNA plasmids encoding different viral proteins and showed success when challenging against lethal influenza (Fynan et al., 1993; Ulmer et al., 1993). These studies were fundamental to understand how DNA could be used for vaccination and thus, protect against a pathogen or an antigen. To date, the scientific community has been striving for the use of DNA vaccines to become a reality around the world.

Since the discovery that DNA vaccines could be valuable tools to generate immune responses, four DNA vaccines have been approved for veterinarian use (Kutzler & Weiner, 2008). In 2005, two prophylactic vaccines against infection with the West Nile Virus in horses and the Hematopoietic Necrosis Virus in salmon were licensed in The United States and Canada, respectively. Following, in 2008, a therapeutic vaccine against fetal loss, which expressed the growth hormone releasing hormone (GHRH), was licensed for use in swine in Australia and in 2010 a therapeutic vaccine to treat oral melanoma in dogs was licensed in the United States. The success of these approved DNA vaccines showed perspectives of an innovative platform to prevent and treat emerging diseases.

STRUCTURE OF DNA VACCINES

DNA vaccines are bacterial-derived plasmids essentially composed of two distinguishable backbones: one for prokaryotic propagation and the other for eukaryotic expression (Liu, 2003). The prokaryotic propagation backbone consists of an origin of replication, which allows the plasmid to multiply during cell division and thus, to be passed on to daughter cells. Additionally, to ensure that all bacterial cells are carrying the plasmid of interest, DNA vaccines have a prokaryotic selectable marker generally consisting of a resistance gene to a specific antibiotic. The eukaryotic expression backbone comprises a transcriptional unit that allows for antigen expression in eukaryotic cells. A constitutive or inducible promoter has to be carefully chosen according to the desired expression, as, for

example, to enhance protein expression and immunogenicity, strong viral promoters, such as the cytomegalovirus (CMV) and Simian Virus 40 (SV40) promoters, are good options. For correct recognition of messenger RNA (mRNA) and initiation of the translation process by the eukaryotic machinery, a consensus sequence, called Kozak sequence, is present after the promoter and includes the start codon (ACCATGG). Following is the coding sequence of the antigen of interest, which is transcribed, translated and, if necessary, post-translationally modified by the eukaryotic host cell. At the end of the gene sequence, there is the stop codon, which follows the correct reading frame to accurately end translation. Finally, the backbone presents the polyadenylation sequence (poly A), which stabilizes the mRNA and ensures that it is exported from the nucleus to the cytoplasm of eukaryotic cells without degradation.

Over the years, strategies aiming at increasing the effectiveness of DNA vaccines have been developed. Because prokaryotes prefer codons that differ from those more frequently used in mammalian cells, in order to achieve optimal expression by the host cells, the coding sequence of the antigen of interest can be adapted for codons with more available corresponding transfer RNA (tRNA) (Wang et al., 2006). Strategies to enhance non-specific and antigen-specific responses and stimulatory cytokines are also encouraged, and include the use of immunostimulatory sequences, co-injection of immunomodulatory plasmids or use of adjuvants (Bode et al., 2011; Marc et al., 2015). Moreover, to increase the number of plasmids that reach the host cell nucleus and, consequently, are expressed, DNA nuclear targeting sequences (DTS) can be added to the eukaryotic backbone of DNA vaccines (Miller & Dean, 2009).

CHARACTERISTICS OF DNA VACCINES

DNA vaccination is a strategy designed to comply with efficient and effective immunization. Clinical trials have shown bottlenecks that need to be improved as well as the advantages of DNA vaccines, highlighting the potential of this innovative vaccination platform (Marc et al., 2015). At first, a recurrent concern was whether plasmids could integrate into the mammalian genome and its consequent unknown implications. However, the probability of plasmid integration into the host genome could be considered negligible, making vaccination with DNA safe (Glenting & Wessels 2005). The time spent to develop and produce DNA vaccines is short, compared to other platforms such as egg-based protein vaccines, and can rapidly be manufactured in large-scale to meet global demands (Moss 2009). In addition, the production of DNA vaccines is inexpensive compared to conventional vaccines, making this vaccination strategy even more attractive. Due to their composition, DNA vaccines are thermally stable, allowing for easy storage and shipping, making it possible to reach locations that do not have the appropriate refrigerated structure storage that some vaccines require (Ghanem et al., 2013).

The ability to elicit humoral and cell-mediated immune responses is one of the main advantages of DNA vaccines. While conventional protein-based vaccines commonly only induce antibody production, this new vaccination strategy can stimulate B and T cells, inducing antibody production and cellular responses, supporting their potential to confer protection against different pathogens (Li et al., 2012). The use of genetic material avoids manipulation of deadly infectious microorganisms and results in more safety during the

production of DNA vaccines. Additionally, the formulation of DNA vaccines allows for the insertion of distinct antigen-coding sequences into the same plasmid, resulting in a broader immune response. Finally, DNA vaccines can be administered through different routes, increasing the range of strategies to reach the desired immunization process (Reyes-Sandoval & Ertl, 2001; Laddy & Weiner, 2006).

MUCOSAL DNA VACCINES

The respiratory, gastrointestinal and urogenital tracts are covered by mucosal surfaces, which are large tissues protected by a highly specialized innate and adaptive immune system. As the majority of infections affect or start at mucosal surfaces, the mucosal immune system can prevent infectious agents from attaching, colonizing, penetrating and replicating, blocking microbial toxins in the mucosal epithelium (Holmgren & Czerkinsky, 2005).

The preferred mucosal routes for vaccination are the vaginal (Kanazawa et al., 2008), intranasal (Brave et al., 2008) and oral mucosae (Chatel et al., 2008). However, the oral route is the most commonly used because the gastrointestinal tract has the largest surface area in the body, with more than 200m² of mucous membrane (Andrew et al., 2011). Thus, the gut-associated lymphoid tissue (GALT) is the largest immune compartment in the body, containing the highest number of immune cells (Schroeter & Klaenhammer, 2009; Mowat & Agace, 2014).

The GALT has two prominent non-encapsulated structures, which are the induction sites of immune responses, known as Peyer's patches (PPs), and isolated lymphoid follicles. Additionally, the effector sites include lymphocytes, dendritic cells (DCs) and macrophages that are also dispersed throughout the epithelial layer and lamina propria (Brandtzaeg et al., 2008; Wells, 2011; Mowat & Agace, 2014).

The GALT is characterized by an overlying follicle-associated epithelium (FAE), with low levels of digestive enzymes and less pronounced villi, and is infiltrated by a large number of immune cells. The most notable feature of the FAE is the presence of Microfold cells (M cells), which are specialized for the uptake and transport of particulate antigens from the lumen into an underlying DC-rich subepithelial dome (SED) region, where they can be presented to the adaptive immune cells. PPs, on the other hand, are macroscopic lymphoid follicles located on the antimesenteric side of the small intestine. They are composed of numerous B cell lymphoid follicles, which are flanked by smaller T cell areas. The mesenteric lymph nodes (LM) drain all these sites and connect the mucosal and the systemic immune systems (Mowat, 2003; Wells, 2011; Mowat & Agace, 2014).

The efficacy of oral DNA vaccines depends therefore on whether the administered agents can survive the gastric and intestinal environments, which include pH-induced degradation, enzymes and diffusion across the mucus layers, and whether their residence time in the intestine is sufficient for interaction with and endocytosis by target cells. Therefore, oral administration of vaccines often requires delivery systems that protect against enzymatic degradation and elimination in the gastrointestinal tract, maintaining their high bioavailability (Chadwick et al., 2009). However, results of experimental approaches have proven difficulty to induce strong intestinal immune responses with a single oral administration

of naked DNA vaccines and development of effective mucosal delivery systems remains therefore an active area of research.

BACTERIA AS A VEHICLE FOR MUCOSAL DELIVERY OF DNA VACCINES

Initially, DNA vaccines consisted in direct immunization with naked plasmid in tissues, which internalized and expressed the immunogenic antigen (Liu et al., 2011). However, to reach significant levels of cellular transfection, very high doses of plasmids and multiple boosts were required (Van Drunen Littel-van den Hurk et al., 2000; Le et al., 2000; Babiuk et al., 2003), mainly due to high DNA degradation and low efficacy to overcome membrane permeability and cellular uptake, resulting in poor gene expression and low immunity (Miller & Dean, 2009). This showed that potent transfection methods had to be developed for the success of DNA vaccines.

In this context, the use of bacteria to transfer vaccine plasmids to mammalian host cells showed to be a promising strategy. In 1980, Schaffner was the first to observe the transfer of DNA from bacterial to mammalian cells, when tandem copies of the SV40 genome, carried by *Escherichia (E.) coli* strains, were transferred to co-cultured mammalian cells (Schaffner, 1980). Since then, many bacterial transfer systems have been developed and improved to transfer plasmid DNA to eukaryotic host cells.

This approach has several advantages, such as (i) protection of the DNA vaccine from physical elimination and enzymatic digestion, (ii) targeting of the inductive sites of the body, allowing stimulation of the immune system and (iii) appropriate stimulation of the innate immune system to generate effective adaptive immunity (Holmgren & Czerkinsky, 2005).

Moreover, bacterial carriers are easy to manufacture and able to maintain the plasmids with high copy numbers. Circumventing the need to co-administrate plasmid selection markers, required for vaccination with naked DNA, stable replication of plasmids can be further improved by the introduction of bacterial genes essential for survival within their host (Pilgrim et al., 2003). Additionally, in contrast to immunization with naked plasmid DNA, no further plasmid purification steps are needed, reducing costs and labor (Schoen et al., 2004; Becker et al., 2008). Furthermore, the World Health Organization (WHO) recommends the use of mucosal vaccines because of economic, logistic and security reasons (Holmgren & Czerkinsky, 2005; Wells, 2011).

IMMUNOLOGICAL ASPECTS OF BACTERIAL DNA DELIVERY TO THE ORAL MUCOSA

After oral administration, bacteria carrying plasmids are recognized by immune cells and intestinal epithelial cells (IECs) coating mucosal surfaces. Some attenuated pathogenic bacteria can invade IECs by the expression of virulence factors (invasins) to deliver DNA vaccines while other bacteria can be sampled by intestinal lamina propria DCs or by specialized epithelial M cells overlying PPs (Weiss & Chakraborty, 2001).

After bacterial delivery, innate immune receptors expressed by IECs and DCs, such as pattern recognition receptors like Toll-like and Nod-like receptors, can respond to some bacterial components, which serve as natural antigens after host cell invasion (Barbosa & Rescigno, 2010). Bacterial recognition by the immune system modulates the innate immune response thus, promoting a robust and lasting adaptive response (Hoebe et al., 2004).

Figure 1. Representation of bacteria-mediated DNA vaccine delivery into intestinal cells. Bacteria enter the host cells and are lysed. The DNA plasmids are released in the cytoplasm and transferred into the nucleus, where expression of the open reading frame (ORF) of interest occurs. After protein synthesis by the host cell machinery, the antigen is processed for immune presentation or for secretion to the extracellular medium, eliciting specific prophylactic immune responses.

Once inside mammalian cells a primary vesicle, the phagosome, involves the bacteria. This vesicle fuses to a lysosomal compartment where bacterial lysis occurs releasing the DNA plasmids that then reach the host cytosol. The DNA vaccines then migrate to the cell nucleus, where the gene of interest is transcribed for subsequent cytoplasmic protein synthesis by the host cellular machinery (Grillot-Courvalin et al., 1999; Schoen et al., 2004). Exogenous antigens are presented on the surface of epithelial cells or secreted to the extracellular medium, where they can be transported by antigen presenting cells (APCs), especially DCs present in lymphoid follicles, to the nearest mesenteric lymph nodes and be presented to naïve T cells, resulting in the induction of specific cellular and humoral immune responses (Figure 1).

The induction of mucosal immunity, in which antigen-stimulated T cells migrate to the systemic blood and then head to other mucosal surfaces, occurs thus, demonstrating the importance of mucosal immunization to protect against pathogens that infect through this route (Brandtzaeg et al., 2008; Mowat & Agace, 2014). Furthermore, plasma cells primed in the mucosa are also attracted to these sites resulting in secretory IgA (sIgA) in the mucosal tissues around the body (Barbosa & Rescigno, 2010). Consequently, effector T lymphocytes and sIgA-producing plasma cells are able to protect the mucosal surfaces. In addition, effector memory cells are also induced, accumulating preferentially in non-lymphoid tissues, especially in the intestinal mucosa (Sallusto et al., 1999).

LACTOCOCCUS LACTIS AS DNA DELIVERY SYSTEM

The non-pathogenic and food-grade bacteria *Lactococcus (Lc.) lactis* is an attractive alternative for mucosal delivery of DNA vaccines. *Lc. lactis* is the lactic acid bacteria (LAB) model, is very easy to manipulate and has a large number of genetic tools developed (De Vos & Simons, 1994; Bolotin et al., 2001). Additionally, as these bacteria have been used for food fermentation and preservation for centuries, the Food and Drug Administration (FDA) considers *Lc. lactis* a generally regarded as safe (GRAS) microorganism for human consumption (Van de Guchte et al., 2001).

Therefore, the use of *Lc. lactis* for mucosal delivery of DNA vaccines can be justified by the fact that this bacteria (i) does not contain endotoxins, such as lipopolysaccharides (LPS), on their cell wall, eliminating the risk of anaphylaxis and can be therefore delivered safely at high doses in immunization programs, (ii) can be easily engineered for DNA delivery (Mercenier et al., 2000; Miyoshi et al., 2004; Wells & Mercenier, 2008; Brondyk, 2009), and (iii) its administration induces high production of antigen-specific sIgA (Neutra & Kozlowski, 2006).

USE OF WILD TYPE LACTOCOCCUS LACTIS AS A VEHICLE FOR DNA DELIVERY

The use of *Lc. lactis* as a potential DNA vaccine delivery system has been successfully shown (Pontes et al., 2011; Chatel et al., 2008). Firstly, in 2006, Guimarães and colleagues used a wild type (wt) *Lc. lactis* strain harboring a DNA plasmid coding for bovine β -lactoglobulin (BLG) to deliver DNA into mammalian cells. Production and secretion of BLG were observed in the intestinal epithelial cell line Caco-2 after its co-culture with the recombinant *Lc. lactis* strain, demonstrating that this bacterium could efficiently deliver a fully functional plasmid into epithelial cells *in vitro* (Guimarães et al., 2006). Then, Chatel and colleagues (2008) confirmed the ability of wt *Lc. lactis* to transfer DNA to mice IECs *in vivo*. This strain demonstrated its ability to translocate the intestinal membrane, as BLG cDNA was detected in the enterocytes of mice immunized with *Lc. lactis* carrying the same eukaryotic expression plasmid (Chatel et al., 2008).

Although these studies successfully demonstrated that *Lc. lactis* can be used as a DNA delivery system, different strategies have been developed to increase the ratio of gene transfer and therefore boost the immune response. One of these strategies includes chemical treatments to weaken bacterial cell walls: glycine-treated *Lc. lactis* NZ3900 showed a higher transfer frequency of a eukaryotic expression plasmid encoding for the red fluorescent protein (RFP) to Caco-2 cells (Tao et al., 2011).

Another approach was a new plasmid (pExu) constructed for DNA delivery using *Lc. lactis*, with a theta origin of replication and the pCMV expression cassette. An *in vitro* assay showed that 15.8% of CHO cells were able to express the *enhanced green fluorescent protein* (eGFP) protein after pExu:egfp transfection. Additionally, *Lc. lactis* MG1363 (pExu:egfp) were administered by gavage to Balb/C mice and the eGFP protein was detected in mice enterocytes (Mancha-Agresti et al., 2016). Also using wt *Lc. lactis* for DNA delivery, a different research group showed that this strain efficiently delivered the pPERDBY reporter plasmid encoding the eGFP to Caco-2 cells *in vitro* (Yagnik et al., 2016).

Furthermore, as described in the following section, a very interesting approach based on the use of recombinant invasive *Lc. lactis* strains have already been successfully demonstrated both *in vitro* and *in vivo*.

RECOMBINANT INVASIVE *LACTOCOCCUS LACTIS* AS DNA DELIVERY VEHICLES

Pathogenic bacteria have refined strategies to overcome host defenses and to interact with the host's immune system. To explore this concept and to increase the ability of lactococci to deliver DNA vaccines, some *Lc. lactis* strains expressing invasins have been constructed and shown to improve DNA delivery (Guimarães et al., 2005; Sleator & Hill, 2006). One such strategy engineered *Lc. lactis* to express InlA from *Listeria monocytogenes*. InlA is a cell wall-anchored protein that binds to the extracellular receptor E-cadherin (Gaillard et al., 1991; Mengaud et al., 1996). The recombinant lactococci (*Lc. lactis* InlA⁺), efficiently displaying the cell wall-anchored form of InlA, showed invasion rates in Caco-2 cells that were approximately 100-fold higher than those of wt lactococci. *In vivo* the invasive InlA⁺ strain also proved its capacity to enter epithelial Caco-2 cells with subsequent GFP expression after oral administration to guinea pigs and delivery of a functional eukaryotic plasmid (Guimarães et al., 2005).

To optimize the use of *Lc. lactis* as a DNA delivery system, a new plasmid (pValac - Vaccination using lactic acid bacteria) of 3,742 bp was constructed. The pValac plasmid consists of the cytomegalovirus promoter (pCMV) and polyadenylation sequences from the bovine Growth Hormone (BGH), which allows for the transcription of the ORF of interest with a PolyA tail that is essential to stabilize the mRNA transcript in eukaryotic cells. The pValac also contains origins of replication for its propagation in both *E. coli* (OriC) and *Lc. lactis* (OriA), and a chloramphenicol resistance gene for selection of strains harboring the specific plasmid. To evaluate its functionality, the gfp ORF was cloned into the pValac (pValac:gfp) and fluorescence was observed after PK15 cells transfection. Moreover, the *Lc. lactis* InlA⁺ strain invaded and delivered the pValac:gfp to Caco-2 cells (Guimarães et al., 2009).

However, the use of the *Lc. lactis* InlA⁺ strain presented a major bottleneck: InlA cannot bind to murine E-cadherin receptors, preventing *in vivo* experiments in these animals and limiting its study only in guinea pigs, which may be difficult to handle and/or expensive (Wollert et al., 2007). In this context and in order to increase the delivery of DNA to mammalian cells (Innocentin et al., 2009), a new recombinant *Lc. lactis* strain, expressing Fibronectin Binding Protein A (FnBPA) of *Staphylococcus aureus*, and that could be used in mice was constructed (Que et al., 2001). FnBPA is a virulence factor, which mediates bacterial adhesion to the host tissue and its entry into host cells (Sinha et al., 1999). FnBPA showed increased interaction and entrance of *L. lactis* in IECs and thus levels of DNA vaccine delivery. *Lc. lactis* FnBPA⁺ and *Lc. lactis* InlA⁺ presented comparable *in vitro* internalization rates by Caco-2 cells. After co-incubated of *Lc. lactis* FnBPA⁺ with Caco-2 cells, the pValac:gfp plasmid was more efficiently delivered than by non-invasive strains (Innocentin et al., 2009). Additionally, this strain was successfully used to deliver DNA vaccines encoding the BLG allergen and GFP *in vivo*, showing to be more effective than the wt strain (Pontes et al., 2012).

Another interesting work was performed using the mutated form of Internalin A (mInlA), which can bind to murine E-cadherin. mInlA was successfully expressed at the surface of *Lc. lactis* and showed higher invasion rates into Caco-2 cells and consequently higher delivery levels of BLG-coding plasmid when compared with the wt strain. Furthermore, *in vivo* studies demonstrated that *Lc. lactis* mInlA⁺ tended to increase the number of mice producing BLG (De Azevedo et al., 2012).

All these engineered strains to be used as DNA vaccine delivery systems represent promising tools for mucosal immunization and the strategy to use *Lc. lactis* to deliver prophylactics plasmids has proved to be relevant and possible. Our research group is currently working on the validation of this strategy in the development of DNA vaccines against tuberculosis, a re-emerging infectious disease that deserves great attention in current researches. This approach could therefore allow the use of *Lc. lactis* as efficient DNA vaccine delivery vehicles in a near future.

LACTOCOCCUS LACTIS AS A DNA VACCINE DELIVERY SYSTEM AGAINST TUBERCULOSIS DISEASE

Tuberculosis (TB), which is caused by *Mycobacterium tuberculosis*, is an infectious disease that affects one third of the global population in its latent form. This, in turn, makes TB one of the main social, economic and public health problems worldwide (Lugo & Bewley, 2008). The only available vaccine for clinical use, the BCG (Bacillus Calmette-Guérin), has a variable efficacy in adolescents and adults, requiring the development of more effective and economically viable vaccines.

In this context, *Lc. lactis* appears as an attractive alternative for a TB DNA vaccine delivery system, because it elicits an immune response as efficient as the other mucosal bacterial DNA delivery systems (Table 1). Moreover, *Lc. lactis* does not present risk in future clinical use when compared to attenuated pathogenic bacteria.

Thus, our research group developed new strategies for DNA vaccination against TB using the invasive *Lc. lactis* FnBPA⁺ strain (Innocentin et al., 2009) and the pValac vaccinal

Finally in 2016, Prósperi developed a *Lc. lactis* strain carrying a multigenic DNA vaccine in which the coding sequences of ESAT-6 and Ag85A were fused [*Lc. lactis* FnBPA⁺ (pValac::e6ag85a)]. After oral administration of this strain to mice, INF- γ , TNF- α and IL-17 levels increased significantly and it was also observed activation of specific cytotoxic T lymphocytes. Additionally, this strategy elicited an antigen-specific mucosal immune response shown by a significant increase in sIgA production in the colons of mice (Prósperi, 2016).

[illegible]

CONCLUSION

The applicability and efficacy of DNA vaccines carried by *L. lactis* strains, administered by mucosal routes, have been successfully established, generating a specific and broad immune response. Therefore, this immunization strategy can be used in research and development of DNA vaccines against other pathogens, with applications in the fields of immunization and immunomodulation.

Chapter 302

BILE SALT HYDROLASE ACTIVITY OF LACTIC ACID BACTERIA: A POTENTIAL FOR HEALTH

Engkarat Kingkaew and Somboon Tanasupawat*

Department of Biochemistry and Microbiology,
Faculty of Pharmaceutical Sciences, Chulalongkorn University,
Bangkok, Thailand

ABSTRACT

Many species of lactic acid bacteria (LAB) were usually found and isolated from various sources such as fermented foods (fermented meats, fermented dairy products, fermented fish, fermented vegetables, fermented fruits, fermented cereals and fermented legumes), dairy products, gastrointestinal tract of humans and animals, plant materials, feces, and sewage. LAB are a major group of probiotics, live bacteria that are good for host health. Several LAB express bile salt hydrolase (BSH) activity. Frequently, the bile salt hydrolase (BSH) activity of LAB have been involved with cholesterol-lowering effects and are exhibited by numerous genera, especially *Enterococcus* (*Ec*), *Bifidobacterium* (*Bf*), *Lactobacillus* (*Lb*), *Lactococcus* (*Lc*), *Leuconostoc* (*Leuc*), *Pediococcus* (*Ped*), *Clostridium* (*Cl*), and *Bacteroides* (*B*). They have shown the ability to lower serum cholesterol. Cholesterol is an essential building block for biological synthesis in the human body (hormone, vitamin D and bile acid) and is the important hypocholesterolemic role of bile salt hydrolase (BSH). One of the reasons that LAB have a hypocholesterolemic effect is bile salt hydrolase production or deconjugation of bile acid. Bile acids are made from cholesterol and amino acids (Taurine or Glycine) and metabolized *de novo* in the human liver via conjugation. Conjugated bile acid then flows into the intestine, where the amide bond of conjugated bile acid react with the bile salt hydrolase (BSH) that is produced by LAB. The amino acids were disintegrated from steroid core, and then transformed into a final form of bile acid is called deconjugated or unconjugated bile acid, which is less effectively reabsorbed than its conjugated form. Deconjugated bile salt results in the excretion of greater amount of free bile acids in feces, that is less solubility and absorption in intestine; therefore, enterohepatic recirculation, the homeostasis of bile acid, and could be consequently dragged into a

* Corresponding Author's Email: Somboon.T@chula.ac.th.

reduction in serum cholesterol by augmentation the demand of cholesterol for *de novo* synthesis of bile acid to substitute those are eliminated in feces or by decreasing cholesterol solubility and thereby absorption of cholesterol through the intestinal lumen.

INTRODUCTION

Cholesterol is an essential building block for maintaining good health; however, hypercholesterolemia has been recognized as a major risk factor in atherosclerosis and coronary heart diseases (Brown & Goldstein, 1984; Khedkar, 1993; Smet et al., 1994). Bile salt hydrolase (BSH) activity of LAB may reduce the serum cholesterol level as suggested by (De Smet et al., 1995; Ahn et al., 2003). BSH enzyme is synthesized by several LAB and hydrolyzes either glycine- or taurine-link bile acids deconjugation reaction. The deconjugated bile acids are less soluble and less reabsorbed than conjugated bile acids, which results in excretion of larger amounts of free bile acids in feces; consequently, the cholesterol is taken up for *de novo* bile acid synthesis to maintain bile acid levels. Therefore, the deconjugation of bile acids by LAB bacteria could lead to a reduction in serum cholesterol (Pereira, McCartney & Gibson, 2003). Bile salt hydrolase (BSH) activity has been detected in many LAB living in the various sources (Jarocki et al., 2014; Ding et al., 2017; Xu et al., 2016; Saravanan & Shetty, 2016; Hou et al., 2015; Du Toit et al., 1998; Tanaka et al., 2000; Grill, Manginot-Durr et al., 1995; Öner, Aslim & Aydaş, 2014; Shekh, Dave & Vyas, 2016; Abushelaibi et al., 2017; Sirilun et al., 2010; Liu et al., 2017; Argyri et al., 2013; Franz et al., 2001; da Silva Ferrari et al., 2016; Elkins, Moser & Savage, 2001; Shehata et al., 2016; Corzo & Gilliland, 1999; Pato et al., 2004; Patel et al., 2010). Additionally, other researchers suggested the importance roles of BSH enzyme so that the bacterial cells can be detoxified of conjugated bile acids for microbial bile tolerance and survival in the intestine, liberating of amino acids from bile acids for bacterial growth, and alteration of bacterial membrane (Tanaka et al., 2000; Tannock, Dashkevich & Feighner, 1989; De Smet et al., 1995; Dambekodi & Gilliland, 1998; Taranto et al., 1998; Taranto et al., 2003).

Furthermore, some studies suggested undesirable effects of bacterial BSH activity on human health. It is possible that the deconjugated bile acids may impair digestive system and colonic mucosal function, play a role in gallstone formation and also cause DNA damage that promotes colon cancer (Jarocki et al., 2014). Thus, the bacterial BSH activity has been included among the criteria for the selection of probiotic strains. However, the bacterial BSH activity has been argued to be potentially harmful to human, and therefore it is as yet not clear whether BSH activity is, in fact, a desirable trait in a probiotic bacterium. This chapter gathered, described and summarized the available literature in the characteristic of bile, bile salt hydrolase (BSH) enzyme, mechanisms of cholesterol-lowering by LAB, bile salt hydrolase producing LAB, the effects of bacterial bile salt hydrolase on hosts and the beneficial effects of BSH activity to bacteria.

CHARACTERISTIC OF BILE AND FUNCTION

Bile is a dark green to a yellowish brown aqueous solution whose major constituents include cholesterol, bile acids, phospholipid, and the pigment biliverdin (Begley, Hill & Gahan, 2006). Bile is produced in the pericentral hepatocytes of the liver, stored and concentrated in the gallbladder interdigestively, and secreted into the first part of the small intestine which is named duodenum. Bile plays an essential role in fat digestion, which acts as a biological detergent, helping to emulsify and solubilize fats in food. Because of its biological detergent and membranolytic activity, bile is also an antimicrobial agent, a feature considered important for inhibiting the bacterial colonization in the proximal small intestine (Tremblay et al., 2017).

Bile acids are hydroxylated steroids. The two primary bile acids are cholic acid and chenodeoxycholic acid that are synthesized *de novo* from cholesterol in the liver. After that, the primary bile acid is also metabolized via conjugation (N-acyl amidation) to taurine (tauroconjugated) or glycine (glycoconjugate). The conjugation in the liver increases the solubility of the hydrophobic steroid nucleus; consequently, these molecules are amphipathic and can solubilize lipid to form mix micelles. Bile acids are conserved by a process named enterohepatic recirculation. Both conjugated and deconjugated bile acids are absorbed via active transport in the distal part of ileum and via passive transport (Kumar et al., 2012). Reabsorbed bile acids flow into the portal bloodstream and are taken up by hepatocytes. Later, reabsorbed bile acids are reconstituted and resecreted into bile. Secondary bile acids are produced by intestinal bacteria. According to Bortolini, Medici & Poli (1997), “approximately 5% of the total bile acid pool (0.3 g to 0.6 g) per day eludes epithelial absorption and may be extensively modified by the indigenous intestinal bacteria.” One of the main bile acids conversions is deconjugation (Batta et al., 1990). Deconjugation is the reaction that hydrolyzes the amide bond and liberates the glycine or taurine moiety from the steroid core. Finally, the bile acids are termed deconjugated or unconjugated.

BILE SALT HYDROLASE ENZYME

Bile salt hydrolase enzyme (BSH) (Cholylglycine hydrolase, E.C.3.5.1.24) has been found and characterized from many bacteria such as LAB, and mammalian gut microbiota. BSH enzyme is responsible for bile acid metabolism and plays a vital role in their colonization and survival in the mammalian intestine or harsh environments. BSHs are characterized as intracellular enzymes which belong to cholylglycine hydrolase family (Patel et al., 2010; Bi et al., 2013). The characteristics of BSHs are oxygen insensitivity, and the optimal pH normally between pH 5 and 6. In addition, one of the important factors is biomass production, since BSHs activity depends on biomass production (Begley, Gahan & Hill, 2005). Furthermore, bile deconjugation also leads to decreasing of serum cholesterol and alterations in energy homeostasis. The presence of an active BSH enzyme has long been considered as a criterion for the selection of potential probiotics (Food & Group, 2002).

MECHANISMS OF CHOLESTEROL-LOWERING BY BILE SALT HYDROLASE OF LAB

Numerous mechanisms to lower cholesterol have been proposed in previous researches, such as enzymatic deconjugation of bile salt by LAB. LAB reducing cholesterol activities are described here. The mechanism of cholesterol-lowering by LAB is to deconjugated bile acids by bile salt hydrolase enzyme. Bile acids are hydroxylated steroids, synthesized in the pericentral hepatocytes of the liver from cholesterol. The primary bile acids, such as cholic and chenodeoxycholic acids, are *de novo* synthesized in the liver and conjugated to either glycine (glycoconjugated) or taurine (tauroconjugated) via an amide linkage at the C24 carboxyl. They are excreted across the canaliculi to the biliary system. Over than 95% of bile acids secreted in bile are reabsorbed in the distal part of ileum and return to the liver because bile acids are conserved under normal condition by a process which is called enterohepatic circulation. In addition, bile acids play an important role in lipid-soluble nutrient and dietary lipid absorption (Korpela, Adlercreutz & Turunen, 1988; Kurdi et al., 2003). Unabsorbed bile acids flow into the colon and then they are catalyzed by bacterial metabolism such as deconjugation with bile salt hydrolase enzyme (BSH) which is generated by LAB. The conjugated bile acids are transformed to the deconjugated form. Most deconjugated bile acids are excreted and found in human feces because of their lower solubility and absorption. Consequently, it causes a reduction in serum cholesterol by increasing cholesterol demand for *de novo* bile acid synthesis to compensate the eliminated part. In a homeostatic response, new bile acids are synthesized from cholesterol for maintaining bile acid level, resulting in decreasing of serum cholesterol (Moser & Savage, 2001; Ahn et al., 2003; Ooi & Liong, 2010; Kumar, Ghosh & Ganguli, 2012; Bi et al., 2013). In conclusion, the BSH enzyme performance has a cholesterol-lowering effect.

BILE SALT HYDROLASE PRODUCING LAB

Bile salt hydrolase activity has been detected in LAB such as *Lactobacillus* (Tannock, Dashkevich & Feighner, 1989; Lundeen & Savage, 1990; Christiaens et al., 1992; Lundeen & Savage, 1992; Bateup et al., 1995; De Smet et al., 1995; Taranto et al., 1996; Du Toit et al., 1998; Elkins & Savage, 1998; Corzo & Gilliland, 1999; De Boever & Verstraete, 1999; Tanaka et al., 1999; Grill et al., 2000; Elkins, Moser & Savage, 2001; Pereira, McCartney & Gibson, 2003; McAuliffe, Cano & Klaenhammer, 2005; Argyri et al., 2013; Hou et al., 2015; da Silva Ferrari et al., 2016; Shehata et al., 2016; Shekh, Dave & Vyas, 2016; Abushelaibi et al., 2017), *Lactococcus* (Pato et al., 2004; Shehata et al., 2016; Abushelaibi et al., 2017), *Bifidobacterium* (Grill, Manginot-Durr et al., 1995; Grill et al., 1995; Grill et al., 2000; Tanaka et al., 2000; Kim et al., 2004; Kim, Yi & Lee, 2004; Kim, BrochetLee, 2005; Jarocki et al., 2014; Öner, Aslim & Aydaş, 2014), *Enterococcus* (Franz et al., 2001; Knarreborg et al., 2002; Veysey et al., 2001; Xu et al., 2016), *Pediococcus* (Xu et al., 2016), *Leuconostoc* (Saravanan & Shetty, 2016; Xu et al., 2016), and also in *Clostridium* (Coleman & Hudson, 1995; Pereira, McCartney & Gibson, 2003), and *Bacteroides* strains (Kawamoto, Horibe & Uchida, 1989; Stellwag & Hylemon, 1976) which have been isolated from traditional fermented foods, dairy, plant, sewage, feces, animal, and the human gastrointestinal tract. The

presence of BSH producing LAB is mostly found in the bile acid-rich environment (Tanaka et al., 1999). Generally, bifidobacteria and lactobacilli are used as probiotic, whereas *Enterococcus*, *Clostridium*, and *Bacteroides* strains are mostly found in the gastrointestinal tract. Numerous studies have reported BSH-positive strains as shown in Table 1.

EFFECTS OF BACTERIAL BILE SALT HYDROLASE ON HOSTS

Cholesterol-lowering Effect of LAB: Hypcholesterolemic Benefits

Hypercholesterolemia is the major risk factors of cardiovascular disease (CVDs) that is the main cause of the mortality (Labarthe & Dunbar, 2012; Roth et al., 2011). The coronary

arteries are affected by high serum cholesterol. Atherosclerosis, the hardening of the arteries, is a condition where the arteries become narrowed and hardened due to a buildup of plaque around the artery wall. Atherosclerosis begins when the endothelium becomes damaged, allowing the harmful type of cholesterol to make up part of the artery wall. Thus, dietary modification and functional foods are becoming an interesting issue to reduce the risk of heart diseases (Aronow, 2013; Lichtenstein & Goldin, 1993; St-Onge, Farnworth & Jones, 2000). Functional food is an interesting alternative choice to manage serum cholesterol due to the effect of LAB or other probiotics. LAB consist as a major group of probiotic bacteria: live bacteria that are good for host health. Several LAB express cholesterol-lowering effects (Jones, 2002).

Even though there have been several medicines for the treatment of hypercholesterolemia, these medicines are expensive and have negative side effects. In these senses, it is possible that the using of BSH enzyme to reduce serum cholesterol levels in the patient with hypercholesterolemia and also prevent hypercholesterolemia in normal people has arisen as an interesting alternative to drugs available today (Chae et al., 2013).

Impaired Digestive Functions

In lipid digestion and absorption, the BSH activity may compromise the mechanisms of lipid emulsification and micelle formation due to lack of conjugated bile acids which are more efficient than deconjugated bile acids (Nagpal et al., 2012). The growth defects in chicken have been found with microbial BSH activity correlation (Walker & Gilliland, 1993; Du Toit et al., 1998). However, there is no association between the growth defects and the BSH activity in mice (Kumar et al., 2012).

Disruption of Intestinal Conditions and/or Gallstones

Several studies have reported that the deconjugated bile acids may disturb colonic mucosal function which would be the causes of diarrhea or inflammation. In addition, it is assumed that colon cancer as a result of DNA damage can be caused by deconjugated bile acids. (Kandell & Bernstein, 1991; Bernstein et al., 2005; Marteau et al., 1995; Nagengast, Grubbenvan & Munster, 1995; Pazzi et al., 1997).

Additionally, the alterations of the bile acids concentration may lead to bile being supersaturated with cholesterol. This cholesterol may precipitate together with calcium salts and bile pigments to form solid build-ups of crystallized bile termed gallstones, which may build up and impede the biliary ducts (Low-Beer & Nutter, 1978; Marcus & Heaton, 1986; Veysey et al., 1999). Interestingly, the increasing deconjugated bile acid formation has been observed in gallstone sufferers (Berr et al., 1996; Mamianetti et al., 1999).

BENEFICIAL EFFECTS OF BSH ACTIVITY TO BACTERIA

Firstly, studies strongly support the hypothesis that bacterial BSH depress the antimicrobial properties of bile acid; consequently, the bacterial BSH producing strains can better survive and persist in the human gastrointestinal tract. Since the deconjugated bile acids have decreased solubility and diminished detergent activity, these can be less toxic to bacteria in the intestine. Secondly, other studies suggested that some bacterial species may be given carbon, nitrogen and sulfur sources by deconjugation with BSH enzyme (Tanaka et al., 2000; Van Eldere et al., 1996; Jarocki et al., 2014). Finally, there is a possibility that the BSH facilitates incorporation of cholesterol moiety or bile into bacterial membranes. This incorporation may probably modify and improve fluidity, permeability and the net charge of the bacterial membranes; consequently, this alteration improves the colonization ability and survival of these microbes in the gut. Because the bacterial cell modification, which is the result from BSH activity, could protect the bacteria from the immune system (Dambekodi & Gilliland, 1998; Taranto et al., 1997; Taranto et al., 2003). However, this incorporation may be the important resistance mechanisms that are the cause of persistent pathogen infection (Begley, Hill 6 Gahan, 2006).

In conclusion, BSH activity is desirable for enhancing the overall probiotic beneficial effects correlated with each strain. For the human supplementation, the safety of administering BSH producing bacteria as probiotic must be considered in order to prevent undesirable side effects (Ahn et al., 2003; Gilliland & Speck, 1977; Takahashi & Morotomi, 1994).

CONCLUSION

Increasingly, it is becoming apparent that microbial BSH activity may confer a selective benefit on probiotic strains in the highly competitive environment of the human intestinal tract. Moreover, the manipulation of BSH activity may ultimately lead to the development of more robust probiotics with improved competitiveness and performance. Finally, targeting the bacterial BSH to modify cholesterol and bile acid metabolisms might be interestingly alternative choices to prevent or treat various diseases such as hypercholesterolemia and cardiovascular diseases.
